*To Edwin S. Shneidman, father of suicidology,
superlative mentor, and friend.*

Preface

This monumental work on the topic of suicide is the result of an array of collaborations, contacts, partnerships, or simply acknowledgment of great scholars' seminal works. It started with the purpose of creativity, to take advantage of the many perspectives about suicide risk that dedicated researchers in this field have studied. Rather than providing a standard approach for editing this book, I started from the people worldwide who represent some references for specific subjects related to the main topic of this book. I have included well-renowned scholars and those that fuel local realities and propose alternative approaches to the traditional ones. In this effort, I maintained the main areas of interest; the reader will find that some differences can be drawn among the chapters. However, that specific subject could be illustrated appropriately according to the author's views. This book was mainly crafted during the first waves of the pandemic, with challenging efforts to deal with both emergency needs and scientific tasks to combine. Despite the many difficulties, I praise the contributors for their strong support in this project.

Suicide remains a major public health issue worldwide, and we are now facing a rapidly changing world. This book is, therefore, a timely contribution to the prevention of suicide with a multifaceted approach.

One of my purpose of this book was to provide a multicultural understanding of suicide and include contributors from worldwide. In this regard, one of the models for building a shared understanding of suicide is represented by approaches that represent a common language in assessing and managing suicide risk. The field of suicide prevention has recognized for decades the lack of a common risk detection method as one of the key impediments to reducing suicide. Many international agencies identified the urgency and worked toward adopting common nomenclature for gathering surveillance data and communication across public health, especially towards making a common suicide screening method available within and outside healthcare. The Columbia Suicide Severity Rating Scale (C-SSRS), developed by a group of suicidologists across several universities in the United States, with its simple, yet comprehensive set of questions, has accomplished unprecedented unification in the field of suicide prevention. Clear delineation of suicidal ideation and behavior types has given the C-SSRS its superior sensitivity to detecting and predicting suicidal behavior. Available in 150 country-specific languages, it has become a global method for suicide risk detection. Large international studies

have provided clear evidence of the scale's ability to identify and predict death by suicide, arguably the most difficult outcome to predict prospectively. It has given the field better risk stratification and triage for imminent risk, which is crucial for person-centered care delivery, enabling screening, triage, and identification of high risk in one step. This has had a profound ripple effect on connecting those who are truly at risk with the care they need, thereby maximizing resource utilization, reducing suicide across all public health sectors, making population surveillance of suicide risk factors more accurate, and improving standards of care and facilitating global suicide prevention policy. From police to universities, it has instilled confidence in suicide risk screening and increased liability protection.

Such an example of a well-receipt tool should be translated into other countless suicide prevention actions, paradigms, and shared decision-making. Increasing awareness of the phenomenon is certainly a major goal, together with reducing stigmatization of the topic of suicide. Besides such actions, a common language in suicidology should be of primary importance. Above all, there should be an emphasis on understanding the drama occurring in the suicidal mind. Without empathic support for those in crisis, the struggle against suicide would be lost.

Finally, this book is dedicated to the memory of Edwin Shneidman, who gave me fundamental suggestions and directions for becoming a suicidologist. Without his teaching, I would never have had the curiosity and strength to explore the topic of suicide, which ultimately put me in connection with others' sufferance and hopefully provided some relief.

Rome, Italy

Contents

Volume 1

Part I	Models of Suicide	1
1	Models of Suicide and Their Implications for Suicide Prevention	3
	David Lester	
2	Neurobiological Approach to the Study of Suicide	13
	Kees van Heeringen	
3	The Journey Back from Suicide	21
	Sylvia Huitson	
4	Suicide as Syndemic	31
	Chris Caulkins	
5	Risk and Protective Factors for Suicide from a Cultural Perspective	45
	Teresita Morfin-López	
6	Protective Factors in Suicidal Behavior	77
	Gerard Hutchinson	
7	Unmet Needs in the Management of Suicide Risk	85
	Maurizio Pompili	
8	Reasons for Living as a Strength-Based Approach to Suicide Prevention	97
	Maryke Van Zyl, Priscilla Phan, Connie Fee, and Sophal Khiv	
9	Prevention-Oriented Risk Formulation	119
	Anthony R. Pisani, Daniel C. Murrie, Morton Silverman, and Kathryn Turner	

10	The Narrative Crisis Model of Suicide: A Novel and Empirically Grounded Diathesis-Stress Model of Suicide	151
	Sarah Bloch-Elkouby, Nadia Yanez, Lakshmi Chennapragada Jenelle Richards, Lisa Cohen, and Igor Galynker	
11	Clinician Emotional Response to Patients at Risk of Suicide: A Review of the Extant Literature	167
	Saskia Newkirk and Igor Galynker	
12	How to Ask About Suicide	183
	Alan L. Berman	
13	Collaborative Assessment and Management of Suicidality Approach	201
	David A. Jobes, Irene Zhang, and Tia Tyndal	
14	Differentiation of Suicidal Behavior in Clinical Practice	219
	Remco F. P. de Winter, Connie Meijer, Nienke Kool, and Marieke H. de Groot	
15	Postdiction in the Psychological Autopsy: A Clue or Algorithm	237
	Antoon A. Leenaars	
16	Suicide and Trauma	269
	Katie J. E. Carlson, Marissa N. Eusebio, Shaune-Ru Wang, and Lisa M. Brown	
17	Suicide and Psychotic Depression	283
	Bianca Eloi, Kevin Rodriguez, Erin O'Connell, Alan F. Schatzberg, and Bruce Bongar	
18	Indirect Self-Destructive Behaviors	295
	Kyle Rosales, Erik Wendel Rice, and Lisa M. Brown	
19	Promoting Healthy Development and Preventing Suicide Across the Life Span: Individuation and Attachment in Matched Biblical and Graeco-Roman Narratives	313
	Kalman J. Kaplan	
20	The Impact of Stigma on the Risk of Suicide	355
	Elena Rogante, Salvatore Sarubbi, and David Lester	
21	The Role of Resilience in Suicide Prevention and for Recovery After Suicide Attempt: Learning from 80 Years of Resilience Research	367
	Anita M. Chauvin	
22	Learning from the Lived Experience of Resilient Survivors of Suicidality and Suicide Attempt: The Role of Self-Managing Recovery in Building Resilience to Future Adversity	391
	Anita M. Chauvin	

Part II Suicide Prevention Across the Life Span	419
23 Treatment Approaches with Suicidal Adolescents	421
Anthony Spirito, Margaret Webb, Jennifer Wolff, and Christianne Esposito-Smythers	
24 Suicide Prevention Among Elderly	443
Diego de Leo, Andrea Viecelli Giannotti, Monica Vichi, and Maurizio Pompili	
25 Suicide and Older Adults: The Role of Risk and Protective Factors	467
Juliet Sobering, Abbie J. Brady, and Lisa M. Brown	
26 Preventing Suicide in Boys and Men	483
Jane Pirkis, Kylie King, Simon Rice, Zac Seidler, Bernard Leckning, John L. Oliffe, Stewart Vella, and Marisa Schlichthorst	
27 The Workplace: Our Most Crosscutting and Under-Leveraged System in Suicide Prevention and Suicide Crisis Response	495
Sally Spencer-Thomas	
28 Suicide Risk Among Psychiatric Patients	509
Erkki Isometsä	
29 Suicide in Doctors	529
Tiago Castro e Couto, Sarah Cristina Zanghellini Rückl, Dante Duarte, and Humberto Correa	
30 Suicidal Risk Across the Life Span	551
Massimiliano Orri, Gustavo Turecki, and Marie-Claude Geoffroy	
Part III Social Aspects of Suicide	577
31 The Aftermath of a Suicide: Social Media Exposure and Implications for Postvention	579
Jo Bell and Chris Westoby	
32 Print Media and Suicide	595
Jean-Pierre Soubrier	
33 Suicide Prevention in Female Sex Workers	603
Alexandre Teixeira	
34 Zero Suicide: The Movement to Safer Suicide Care in Health Care	615
Julie Goldstein Grumet, Michael F. Hogan, David Covington, and C. Edward Coffey	
35 Suicide Prevention: Turning Inward for Direction	645
Daniel J. Reidenberg	

36	Life Skills Dynamic Meditation for Suicide Prevention	655
	Pandit Devjyoti Sharma	
37	Complex Trauma and Suicide: An Integrative Interpersonal Approach	681
	Kayleigh N. Watters, Jessica T. Sklar, Sloane R. M. Rickman, and Matthew M. Yalch	
38	Suicide and Suicidal Ideation During the COVID-19 Pandemic	691
	Karen Wetherall, Seonaid Cleare, Tiago Zortea, and Rory C. O'Connor	
39	Population Density and Suicide Risk	703
	Benedetto Vitiello, Monica Vichi, Chiara Davico, Silvia Ghirini, and Maurizio Pompili	

Volume 2

Part IV	Suicide in Different Cultures	717
40	Suicide in South Asia	719
	Lakshmi Vijayakumar and Madhumitha Balaji	
41	Cultural Considerations in Suicide Research and Practice	739
	Paola Mendoza-Rivera, Helen Ma, Bruce Bongar, and Joyce P. Chu	
42	The Roles of Culture, Race, and Ethnicity in Suicide	757

About the Editor

Maurizio Pompili, M.D., Ph.D., is Full Professor and Chair of Psychiatry as part of the Faculty of Medicine and Psychology at Sapienza University of Rome, Italy, where he received his M.D. degree and trained in Psychiatry (both *summa cum laude*). He is the Director of the Residency Training Program in Psychiatry of his faculty.

Prof. Pompili is the Director of the University Psychiatric Clinic and the Director of the Suicide Prevention Center at Sant'Andrea Hospital in Rome. He is the President of the Psychiatric Rehabilitation Technique degree program at the Sapienza University of Rome. He has a doctoral degree in Experimental and Clinical Neurosciences. He was also part of the Community at McLean Hospital – Harvard Medical School, the USA, where he received a psychiatry fellowship. He is the recipient of the American Association of Suicidology's 2008 Shneidman Award for "Outstanding contributions in research in suicidology."

Apart from being the Italian Representative of the International Association for Suicide Prevention (IASP) for many years, he has been afterward one of the Vice-Presidents of this association. He is now Co-Chair of the IASP Special Interest Group in Risk Resilience and Reasons for Living. At present, he is a member of the IASP Executive Committee in the role of treasurer. He is also a member of the International Academy for Suicide Research and the American Association of Suicidology and is also President of the Suicidology Section of the Italian Psychiatric Society.

He has published more than 550 papers on suicide, bipolar disorders, and other psychiatric perspectives, including original research articles, book chapters, and

editorials, and has co-edited 10 international books on suicide.

Prof. Pompili ranks in the top 10 suicide authors of 500 world suicide authors listed in the ISI Web of Science (this is in terms of the number of focused works on the topic of suicide that are indexed in the ISI Web of Science). He has been recognized by Expertscape as an expert in suicide, ranking 1st worldwide.

Abstract

Suicidal behavior is highly complex and multifaceted. Consequent to the pioneering work of Durkheim and Freud, theoreticians have attempted to explain the biological, social, and psychological nature of suicide. The present work presents an overview and critical discussion of the most influential theoretical models of the psychological mechanisms underlying the development of suicidal behavior. All have been tested to varying degrees and have important implications for the development of therapeutic and preventive interventions. Broader and more in-depth approaches are still needed to further our understanding of suicidal phenomena.

Theories of suicide · Suicide prevention · Durkheim · Hopelessness · Attempted suicide

Explanations for suicide must account for two phenomena. First, societal suicide rates vary widely from nation to nation, over regions within a nation (such as the states of the USA), and among the different groups in the population (e.g., by sex, age, and ethnicity), as well as over time. Second, explanations must be found for the occurrence of suicide in individuals, a task which has proven to be more difficult than explaining the societal suicide rate. The difficulty in explaining individual suicidal behavior results in part because there appear to be no physiological, psychological, or interpersonal variables that are necessary or sufficient to account for suicide. For example, although suicide may be more common in those with terminal illnesses, a terminal illness is neither necessary nor sufficient for suicide to occur. An analogy here is the decay of radioactive atoms. Physicists can predict what proportion of atoms will decay over time (e.g., the half-life of uranium-235 is about 700 million years) but not which particular atom will decay next [17]. A behavior, predictable at the societal/aggregate level, can be unpredictable at the individual level.

Sociological Models

The major sociological model of suicide is that of Durkheim [4] who proposed that the societal suicide rate is determined by social integration (the extent to which the members of the society are bound together in social networks) and social regulation (the extent to which the values, desires, and behaviors members of the society are regulated by societal norms). Too little of these factors increases the risk of egoistic and anomic suicide, respectively, and too much of these factors increases the risk of altruistic and fatalistic suicide, respectively. There have been serious criticisms of this theory (see [15]), but these criticisms are not pertinent to the present discussion.

A second theory came from Henry and Short [9] who saw suicide and homicide as alternative behaviors for dealing with frustration. When external constraints on behavior are strong, then outwardly directed aggression is legitimized, and homicide will become more common, whereas when external constraints on behavior are weak, then outwardly directed aggression is not legitimized, and consequently inwardly directed aggression will become more common. For example, in a society with two groups, the group that is more oppressed will have higher rates of homicide, whereas the oppressors will have higher rates of suicide [19]. Henry and Short applied their theory to the business cycle [21] which has implications for preventing suicide. (There are other sociological theories of suicide focusing on network ties [29], status integration [6], social strains [39], and religious commitment [36], among others.)

It has been debated whether these sociological theories can be applied to individuals. Henry and Short argued that theory could be applied at the individual level and, for example, they hypothesized that love-oriented punishment would result in the inhibition of outwardly directed aggression (and an increased risk of suicide), whereas physical punishment would not lead to any inhibition of outwardly directed aggression (and, thus, an increased risk of homicide). With respect to Durkheim's theory, Reynolds and Berman [33] examined 404 suicides and were able to classify 56.7% as anomic, 8.7% as fatalistic, 5.7% as egoistic, and 0% as altruistic, with 29.0% as unclassifiable. Lester [18] examined 30 famous suicides whose lives he had examined and found that all could be classified into Durkheim's four categories, although 9 cases seemed to be mixed types (e.g., anomic and egoistic). Perhaps, therefore, Durkheim's sociological theory of suicide can be applied to individuals.

Interestingly, these two theories have not formed the basis for strategies for preventing suicide. There are no suicide prevention programs that have focused on developing moderate (rather than extreme) levels of social integration and regulation in the society, nor on developing moderate levels of external constraints in the society. There are, however, suicide prevention strategies that have focused on the society as a whole (rather than on individuals at high risk for suicide), and these will be discussed below.

Individual Models

Physiological Models

Physiological research into suicide is popular today, but much of this research is a side issue in studies of affective disorders and schizophrenia which were the primary reason for the research, and the results have not yet produced a validated model. For example, the neurotransmitter serotonin has been implicated in the presence of major depressive disorders, and medications (such as SSRIs) have been produced to change the level of serotonin in the brain. However, serotonin has also been implicated in anxiety disorders, eating disorders, and violent impulsive behavior, and SSRIs are frequently prescribed for patients with these disorders. Thus, the impact of serotonin may not be specific to suicide but may be more widespread. Second, although serotonin may perhaps play a role in affecting the risk of suicide, it does not play a role in the choice of method for suicide, the timing of the suicidal act, the precipitating factors, etc. Third, if suicides are found to have abnormal levels of serotonin, we cannot be sure whether this abnormality is a consequence of the suicidal process or the affective disorder.

Physiological models of suicide suggest the use of physiological modifications which, these days, primarily entails medications. However, recent writings have begun to seriously question the scientific basis of the psychiatric classification of disorders which is based primarily on symptoms rather than causes ([20], pp. 21–28) and on the ineffective and often damaging effect of the medications prescribed for those with a psychiatric diagnosis [7, 11]. Clearly, however, physiological strategies

for preventing suicide are applied to the individual rather than the society as a whole. (Research shows that the higher the level of lithium in drinking water over regions, the lower the suicide rate (e.g., [28]), but no one has yet proposed adding lithium to drinking water supplies!)

Intrapsychic Models

It is commonly known that the simple version of a psychoanalytical theory of suicide is that anger felt toward others is repressed and turned inward onto the self. Litman [24] provided a formal model of suicide from this perspective. Litman suggested that (1) the suicidal person has typically lost someone, usually in childhood, (2) part of the person's ego identifies with this lost object who then becomes part of the permanent part of the self, and (3) the person harbors hostile feelings toward the lost object and these hostile desires are turned inward onto the self (see also Menninger [26]).

With the growth in the popularity of cognitive therapies in the 1980s, cognitive theories of suicide began to appear. The most successful theories were stimulated by the development of a measure of hopelessness developed by Beck [1], after which hopelessness has been shown to be one of the most powerful and consistent predictors of suicide (e.g., [22]). More recently, Joiner [13] proposed two factors (thwarted belonging and perceive burdensomeness), along with an experiential factor (the acquired capacity for self-harm), and his theory has received a great deal of empirical support, along with serious criticism [10].

These types of models require the detection of individuals at risk for suicide and then providing effective psychotherapy for them if they desire this. Although there are some validated approaches here, such as the Collaborative Assessment and Management of Suicidality (CAMS) from Jobes [12] (see <https://cams-care.com/about-cams>), there has been a growing awareness that detecting individuals at risk for suicide, even if they are willing to be screened with a battery of psychological inventories, has not advanced in accuracy over the past 50 or more years [2, 5]. (It should be noted that there have recently been serious criticism of the methodological soundness and biased reporting of clinical trials of antidepressants [30].)

Intrapersonal Models

Research on the role of interpersonal relationships in suicidal behavior in recent years has focused on distal variables such as childhood loss, birth order, and the perception of people's relationships with others (rather than direct observation of these relationships and talking to these others). There are some exceptions such as the study of suicide pacts and suicide in small subcultures (such as the description of five suicides in a group of young people in a rural town in Pennsylvania [14]). The role of the family has been described by family therapists such as Richman [34].

Why Are Models of Suicide Important?

Models of suicide are important in two ways. First, they can provide typologies of suicidal individuals, clinical descriptions of each type, and psychotherapeutic tactics for each type. Unfortunately, these models (and other theories of suicide) have not provided typologies that have gained wide acceptance, and so researchers and clinicians usually fall back on psychiatric diagnosis to classify cases.

Second, the models do suggest strategies for preventing suicide, at least for individuals at high risk of suicide, such as medications, individual psychotherapy, and family therapy. However, clinicians are more likely to be guided by the system of psychotherapy in which they were trained rather than by specific models of suicide.

Preventing Completed Suicide

The question, then, is which tactic promises the better payoff: the societal approach or the individual approach.

The Societal Approach

The advantage of the societal approach to suicide prevention is that it reaches everyone in the society (or, at least, a large proportion of the population). For example, Clarke and Lester [3] advocated situational suicide prevention, that is, making it harder to commit suicide by fencing in suicide venues, detoxifying car exhaust, passing stricter gun control laws, etc. If car exhaust is made less toxic, then this “suicide-proofs” the environment for everyone. (Indeed, it would be impossible to detoxify car exhaust, e.g., only for car owners at risk for suicide.)

On the other hand, a societal approach may not be cost effective for suicide is rare, no matter how stressful life is. Thus, society-oriented suicide prevention tactics operate on the vast majority of individuals who are not and never will be suicidal. For example, if we were to add put lithium (or SSRIs) in the water supply to prevent depression and suicide, we would be wasting the medication on millions of individuals who are not at risk for suicide.

The relevance of this argument depends upon one’s theory of suicide. Is suicide rare because, although everyone is a potential suicide, the combination of suicidogenic forces comes together to produce suicide only rarely; or is suicide rare because only a few members of the society are suicide-prone no matter how many and which suicidogenic forces come together? The rarity of an outcome does not necessarily mean that only a few individuals in a society are susceptible. For example, viral meningitis is rare, but it makes sense to immunize everyone against it.

Supporting the theory that suicide proneness is rare, Levy [23] noted that the majority of suicides on a Shoshone-Bannock Native American reservation came

from only eight families and that none of the completed suicides had made prior suicide attempts. These eight families had been labeled as deviants by their peers and had become scapegoats for the society. Designing a suicide prevention program for the whole reservation would be a waste of effort. An effective suicide prevention program for this society would not focus on the community as a whole, but rather on the individuals in these eight families. However, to do this might reinforce their deviant status still further and increase their risk of suicide.

One problem with taking a societal approach is that it is impossible to have much impact on the social forces causing suicide. If suicide is less common in Muslims than in Christians, we cannot convert people to Islam in order to prevent suicide. A similar problem arises when we consider the associations between birth, marriage, and divorce rates and suicide. Individuals cannot be forced into marriage and to have children simply to prevent suicide. On the other hand, the documented association between unemployment and suicide [31] can be used to tailor social policies to promote employment and reduce the unemployment rate. Similarly, if bullying increases the risk of suicide in bullied individuals, then programs to reduce bullying in the society (or in subgroups of the society, such as school children) might have an impact on suicide. Other societal tactics, such as shaping those who report suicide in the media into reporting suicide more responsibly, may also have an impact on suicide in the society.

The Individual Approach

The individual approach focuses on the detection and treatment of those at risk for suicide. This raises two problems. First, detecting those at risk for suicide is very difficult. Indeed, suicidologists have given up deriving suicide prediction scales and now focus instead on “assessing” those who voluntarily come for treatment [25].

On the other hand, the establishment of suicide prevention centers for those in crisis, together with the availability of adequate numbers of psychotherapists skilled in systems of therapy that have been shown to work with suicidal individuals [38], means that individuals can voluntarily contact such resources and receive help. Surveys indicate that large proportions of the population have been suicidal and have had a psychiatric disorder. For example, Roberts et al. [35] found that 10% of school youths aged 10–17 had attempted suicide and have had a psychiatric illness. Regier et al. [32] found that one-third of the American adult population had been psychiatrically ill. Thus, a large proportion of the population may be in need of individual services.

However, providing individual services in appropriate amounts may require actions at the societal level. For example, funds may need to be allocated by the central or regional governments for the establishment of mental health services or for reimbursing counseling and psychotherapy through medical insurance. Thus, public policy may remain the best avenue for preventing suicide.

Comment

It is noteworthy that two of the societal strategies for preventing suicide have odd features. Although suicide prevention centers were established for suicidal individuals, many callers to the telephone services were in crisis but not suicidal. To prevent these people from being deterred from calling, many services changed their name to crisis intervention centers or opened separate telephone lines for “problems in living.” (When I worked at a suicide prevention service, it was not uncommon for callers to say, “I’m not suicidal, so is it ok for me to call you?” We, of course, said yes, but soon opened a “problems in living service.”)

Second, the strategy for preventing suicide by restricting access to lethal methods for suicide was often introduced for different reasons. Natural gas became cheaper (and more environmentally friendly) than coal gas, and so domestic gas was changed, thereby preventing suicides from easily using coal gas for suicide. Emission controls for cars were introduced to reduce pollution, and gun control is more often introduced to prevent murder (and especially mass murder) rather than to prevent suicide.

Preventing Attempted Suicide

The prevailing view today is that completed and attempted suicides are different behaviors, although there is some overlap between the two populations. It has long been argued that studying completed suicide by studying attempted suicides (the method of substitute subjects [27]) is invalid (e.g., [37]). Therefore, because most of the research on individual suicidal behavior focuses on attempted suicides, we know less about completed suicides, for whom the research relies on psychological autopsy studies (which are time-consuming and relatively rare) and studies of suicide notes (left by only a quarter to a third of suicides).

Lester et al. [22] argued that, if we classified a sample of attempted suicides into three (or more) groups based on the lethality of their attempt or the seriousness of their intent, then we could extrapolate any trends to completed suicides (who obviously made the most lethal attempts and with the most serious intent).

However, the strategies for preventing attempted suicide may have to be different from the strategies for preventing completed suicide. For example, in England, restricting the quantity of pills in packages of acetaminophen (Tylenol and paracetamol) and placing the pills in plastic blisters may have reduced the use of those pills for attempting suicide [8], but few completed suicides die from using acetaminophen.

Final Comment: Is Suicide Prevention Needed?

In an editorial meant to be provocative, Lester [16] noted that programs that target bullying in children and adolescence, and the physical, sexual, and psychological abuse of children, or that seek to increase the self-esteem of school children might

prevent suicide later in the lives of these children. If we understood the factors that increase the risk of suicide, then it may make sense to target these factors rather than waiting for the factors to have their deleterious impact. Prevention rather than intervention might be preferable.

Introduction

Rates of suicidal behaviour decrease in many countries in parallel with the development of prevention strategies, but many other countries, including the USA and the UK, are confronted with increases in rates of fatal and nonfatal suicidal behaviours, in spite of preventive efforts. Major obstacles to the prevention of suicide include the difficulty to assess suicide risk and the absence of clear targets for its treatment. Recent neurobiological studies of suicidal behaviour address these obstacles and thus yield promising results for suicide risk assessment and prevention.

Many studies indeed indicate an effect of neurobiological factors on the occurrence of suicidal behaviour [13]. These studies include epidemiological observations of higher suicide rates in association with geographical and environmental characteristics, such as living at higher altitude, air pollution, spring season, fewer hours of sunshine, toxoplasmosis infection and lower levels of lithium in drinking water [3]. Genetic studies show considerable heritability of suicidal behaviour. Studies in molecular and systems neuroscience reveal further evidence of a neurobiological involvement in suicidal behaviour.

Following an introductory section addressing causes and explanatory neurobiological models of suicidal behaviour, this chapter will, first, review studies of underlying neurobiological mechanisms in the domains of molecular, cognitive, systems and developmental neuroscience, respectively. Second, implications for the identification and treatment of suicide risk will be discussed, thus showing the ways in which neurobiological studies can contribute to the prevention of this major public health problem.

Explanatory Neurobiological Models of Suicidal Behaviour

Suicidal behaviour is never the consequence of one single cause. Multiple causes have been identified, which can be classified according to their proximal or distal nature [14]. Proximal causes include psychiatric disorders, such as depression, schizophrenia and alcohol dependence, which are thought to be present in a vast majority of suicides in the Western world. Individuals who have been diagnosed with a psychiatric disorder have a nearly eightfold greater risk of suicide than those who have not [12]. In addition, suicidal behaviour is commonly precipitated by psychosocial stressors, such as relational, professional or financial problems. However, the vast majority of individuals suffering from psychiatric disorders or exposed to severe life events will not take their own lives. Thus, something more than psychiatric disorders or stress is needed to explain the occurrence of suicidal behaviour. Such necessary additional explanatory factors are described as distal or predisposing characteristics. Epidemiological studies show that such characteristics include genetic factors and early-life adversity (ELA). The heritability of suicide is estimated at 30–50%, and a familial history of suicide is an important risk factor for suicidal behaviour in offspring [11]. Neuroscientific research clearly shows the devastating consequences of ELAs (including childhood physical and sexual abuse) that leave

scars in the brain that induce or increase the vulnerability to suicidal behaviour. The molecular and brain correlates of these distal risk factors will be discussed below.

Stress-diathesis models describe the interaction between proximal and distal risk factors. The traits that are produced by a genetic disposition or induced by ELAs constitute the diathesis, and these traits can be described in clinical, neurocognitive and neurobiological terms. Clinical stress-diathesis models describe suicidal behaviours as the consequence of simultaneously present mental pain (induced by proximal precipitants) and (trait-dependent) hopelessness. Emotional pain that is perceived to be without end, in general, is the common motivation for suicide in depressed individuals. Several cognitive stress-diathesis models have been proposed in the past decades, including Williams' 'cry of pain' model that is clearly linked to changes in brain functions, such as attention and memory. The remainder of this chapter will focus on neurobiological models by describing the results of the neuroscientific study of suicidal behaviour.

The Neuroscience of Suicidal Behaviour

Molecular Neuroscience

The study of the mechanisms by which neurons express and respond to molecular signals has revealed functional changes in several brain systems in relation to suicidal behaviours, including stress-response, neurotransmission, neuroinflammatory and neurotrophic systems. Given the role of stressors in the precipitation of suicidal behaviours, the involvement of stress-response systems comes as no surprise. For example, suicide and the stress hormones are related. In addition to an increased suicide risk among individuals taking oral glucocorticoids, studies have consistently shown an attenuated cortisol response following exposure to social stress in self-harming individuals, offspring suicide attempters and relatives of suicides [1]. Genetic influences thus appear to be involved, and it has become clear that ELAs exert their effect on suicide risk via epigenetic changes in the expression of glucocorticoid receptor genes. Since early studies in the seventies, changes in the serotonin (5-HT) neurotransmission system in association with suicidal behaviour have been documented extensively, using a wide range of methodologies in different populations [13]. These changes involve 5-HT receptors (such as the 5-HT_{1A} and the 5-HT_{2A} receptors) and the 5-HT transporter (5-HTT). In keeping with the stress-diathesis approach, an interaction between stress and the 5-HTT gene has received wide attention. Despite inconsistencies in results, a majority of studies indicate that the 5-HTT genotype may moderate the effect of stress on the occurrence of suicidal behaviour. While there is little empirical support for a role of dopamine in suicidal behaviour, the potential suicide risk-lowering effect of ketamine suggests a role of glutamate/GABA neurotransmission. Post-mortem and brain imaging studies indeed provide support for such a role, but underlying mechanisms remain unclear [6].

Based on epidemiological observations of increased suicide risks in inflammatory and autoimmune diseases, such as *Toxoplasmosis gondii* infection, asthma, allergies and lupus, neuroinflammation has become a topic of interest and relevance for suicide prevention. Molecular studies indicate dysregulation of the immune system and cytokines in suicidal behaviour. Activation of the kynurenine pathway of catabolism of tryptophan (a 5-HT precursor) via microglia in particular brain areas is a potential neurobiological mechanism linking inflammation, serotonin and suicidal behaviour [13]. IL-6 signalling is associated with suicide risk [5]. These findings may have clinical implications, highlighting the potential of anti-inflammatory approaches as a putative strategy for suicide prevention. Such approaches may include IL-6 blockade and drugs targeting kynurenine pathway enzymes.

Structural brain changes in association with suicidal behaviour (see below) are thought to be related to the alterations in neurotrophic characteristics, such as BDNF and its TrkB receptor, that are found in suicidal behaviour. Genetic and epigenetic underlying mechanisms have been identified [6]. Interestingly, the lower the level of neurotrophins, the higher the levels of suicide risk, stress and inflammatory markers appear to be [7].

Cognitive Neuroscience

Processing information from the outside world and determining how to use that information may increase adaptive strength. The cognitive neuroscience of suicidal behaviour shows however that changes in these cognitive processes may lead to premature death. The most striking findings are reported with regard to attentional and schematic control and value-based motivational processes. With regard to attention (defined as the selection of relevant information and thoughts), most, though not all, studies have found abnormalities in association with suicidal behaviour, particularly when using the suicide Stroop task. Suicide-related changes in schematic control, i.e., the control over thoughts and actions by beliefs about the self, the world and the future, are reflected by increased implicit associations between ‘death’ or ‘suicide’ and ‘me’, as assessed with the Implicit Association Test (IAT). The IAT predicts suicidal behaviour in some but not all prospective studies [6].

Individual studies, systematic reviews and meta-analyses consistently document decision-making deficiencies in association with suicidal behaviours, particularly when assessed with the Iowa Gambling Task. It is currently unclear how this association should be interpreted. It could well be that deficient more complex decision-making capacities are due to basic neuropsychological dysfunctions, such as attentional biases. They may also reflect an inability to conceptualize problems at a higher abstract level, which may inhibit the exploration of alternative solutions [13]. It should be noted that impaired decision-making and related brain circuit changes are also observed in healthy relatives of people who died from suicide, consistent with familial transmission of an endophenotype for suicide risk [6].

Systems Neuroscience

Structural and functional changes in the brain in association with suicidal thoughts and behaviours have been documented in more than 100 individual studies, systematic reviews and meta-analyses. Most recent findings regarding structural brain changes suggest that impairments in medial and lateral ventral prefrontal regions and their connections are important in the excessive negative and blunted positive internal states that can stimulate suicidal ideation and that impairments in a network consisting of the dorsolateral prefrontal cortex and the inferior frontal gyrus are important in suicidal behaviour. A combination of ventral and dorsal prefrontal system changes may lead to very high-risk circumstances, in which suicidal ideation is converted to lethal actions via decreased top-down inhibition of behaviour and/or maladaptive, inflexible decision-making and planning. The dorsal anterior cingulate cortex and insula may play important roles in switching between these ventral and dorsal systems, which may contribute to the transition from suicide thoughts to behaviours [9].

Functional imaging studies have looked at resting state brain characteristics of suicidal behaviour and at brain correlates of neurocognitive changes and suicide risk factors. Resting state studies have been performed using MRI, PET and SPECT. In general, resting state activity appears to be lower in frontal regions in suicide attempters when compared to controls and in high-lethality attempters when compared to low-lethality attempters. Studies of the serotonin system, e.g., using ligands for serotonin receptors, particularly show increased binding at 5-HT_{1a} receptors in the raphe nuclei in suicide attempters, predicting greater lethality of subsequent suicidal behaviour during follow-up. Other resting state neuroimaging studies have looked at particular characteristics of suicidal behaviour, such as brain correlates of mental pain and concrete suicide plans. These studies suggest a pivotal role of the frontopolar cortex in suicidal behaviour. Given the uniquely human nature of suicidal behaviour, it is noteworthy that the frontopolar cortex has developed disproportionately in humans when compared to other primates, so that its involvement in purely unique human behaviours may not come as a surprise. It appears that suicide risk requires the integrity of this brain area: veteran soldiers who survived a penetrating brain injury in the frontopolar cortex show less suicidal thoughts than veterans who survived a penetrating brain injury in other brain areas, while pessimistic future thinking in depressed individuals is associated with increased activity in this area [17].

Lower functional connectivity is found in adolescent and adult suicide attempters, predominantly in the default mode network, which is implicated in self-referential processing and social cognition. This functional circuitry deficit maps onto the DTI-identified structural connectivity deficits in default mode network hubs and connections [6].

Several functional neuroimaging studies have looked for brain correlates of sensitivity to social stressors in suicide attempters. These studies used fMRI and exposure to signs of others' disapproval or to social exclusion with, e.g., exposure to angry faces and the Cyberball game. Brain responses to such exposures to perceived

adversity appear to be impaired in regions previously implicated in pain tolerance and social cognition. Recent suicidal behaviour seems associated with a distinct neural response to social exclusion independently of presence of depression or suicidal thoughts [2].

A final noteworthy neuroimaging approach to suicidal behaviour has focused on brain correlates of the disturbed decision-making in association with suicidal behaviour as described above. Comparative studies in euthymic suicide attempters reveal altered processing of risk under conditions of uncertainty, associated with left lateral orbitofrontal dysfunction [13].

Neurobiology for Suicide Prevention

In the context of a discussion of the consequences of findings from neurobiological studies for suicide prevention, it is important to address possible causes of disturbances. It has become clear that causes may include genetics and early-life adversities (ranging from poor foetal growth to sexual abuse). Human genetic studies have shown that suicidal behaviour may run in families, although the heritability of suicidal behaviour and ideation is moderate. However, heritability is independent of that of major psychiatric syndromes, and it is mediated by many gene variants of small effect. Suicide-related genes are associated with inflammation, the hypothalamic-pituitary-adrenal (HPA) axis, glutamate neurotransmission and neurogenesis [6]. Disturbed neurodevelopment appears to be an important pathway linking early-life adversities and subsequent suicidal behaviour [8, 10]. Functional and structural brain changes, due to poor development, inflammation or traumatic life events, may play a central role in the diverse pathways leading to suicide. This does not mean that suicide is to be seen as a neurobiological phenomenon. Reviewed studies indicate that neurobiological changes may exert their influence on the occurrence of suicidal behaviour by determining the emotional impact of precipitating stressors and the strategies to cope with adverse circumstances. Neurobiology may thus help to understand the development of the mental state characterized by the emotional pain and feelings of hopelessness that are the common motivation for suicide.

The increasing insight in the nature and causes of neurobiological changes may contribute to suicide prevention not only by increasing insight in the development of suicidal thoughts and behaviours but also by identifying targets for the prediction and treatment of suicide risk. The identification of neural signatures of suicidal thoughts and behaviours provides a promising contribution to suicide prevention, even when suicidal ideation is denied or unrecognized [6]. For example, recent studies using machine learning and neuroimaging data, whether or not combined with cognitive data (e.g., implicit associations), show good accuracy [4, 15].

Reviewed neurobiological studies also provide promising new avenues to the treatment of suicide risk. From a molecular neuroscience point of view, evidence is accumulating that drugs targeting the serotonin, glutamate, opioid and stress-response systems may help prevent suicide. Serotonergic antidepressants may help prevent suicide by effects on depression and anxiety and on the vulnerability to

suicidal behaviour by reducing hopelessness and enhancing cognition [6]. The relevance of lithium and clozapine for suicide prevention has been clearly demonstrated, although involved molecular mechanisms still are unclear. Anti-apoptotic effects of lithium may increase volumes of brain areas in which hypoactivity and cortical thinning are implicated in suicidal behaviour [13]. Intravenous ketamine is a rapidly acting treatment targeting the glutamate system that reduces suicidal ideation in hours instead of weeks. Intranasal ketamine (or esketamine) also shows promise as anti-suicidal ideation treatment and is less invasive, but, like intravenous ketamine, it must be administered in medical settings [6]. Buprenorphine targets the opioid system and has been shown to reduce suicidal ideation in 2 weeks, possibly through diminishing emotional pain [16]. Further study is clearly and urgently needed. A similar urgent need exists with regard to drugs targeting the stress-response system and anti-inflammatory drugs of which some (e.g., minocycline and celecoxib), though not all (e.g., mifepristone and ketoconazole), may show anti-depressive effects [6].

From a systems neuroscience point of view, there is a rapidly increasing interest in neurostimulation targeting delineated brain areas involved in suicidal behaviour. ECT has been shown to rapidly reduce suicide risk in depressed individuals, but the quality of studies is limited, and its use is hampered by fears of side effects. Therefore, interest in the effects of more localized neurostimulation techniques on suicide risk is increasing rapidly. A number of studies demonstrate rapid reductions in suicidal ideation, following repetitive transcranial magnetic stimulation of the dorsolateral prefrontal cortex, although placebo effects cannot be ruled out [13].

Discussion

Epidemiological characteristics of suicidal behaviours suggest a neurobiological influence on their occurrence. This review of recent neuroscientific studies confirms such an influence by describing the changes in brain biochemistry, structures and functions in association with suicidal behaviour, which have been demonstrated in hundreds of good-quality studies. Moreover, this review sheds light on potential causal mechanisms. Suicidal behaviour is associated with neural circuitry dysfunction that may be due to neuroinflammation, disturbed neurotrophic characteristics and/or abnormalities in the stress-response system. A disturbed neurocircuitry may become manifest via impairments in memory, attention and decision-making that constitute the vulnerability to suicidal behaviour. Neurobiology contributes to suicide prevention by, first, offering increasing insights in the mechanisms linking distal influences (such as familial genetic loading and early-life adversity) and suicidal behaviour. Second, neurobiology can contribute to suicide prevention by providing answers to a crucial unmet need, i.e., the prediction of suicidal behaviour via the identification of neural signatures of suicidal behaviour. Third, neurobiology can contribute to the treatment of suicide risk by defining functional and structural brain correlates of suicidal behaviour that are amenable to interventions, be it via psychotherapy, pharmacotherapy or neurostimulation.

The Journey Back from Suicide

3

Sylvia Huitson

Abstract

In 1977, I was a normal well-adjusted person with no mental health issues. Then I made a massive mistake and felt like I had dropped down a rabbit hole to an alternate reality. I struggled to try and make the alternate reality work for 10 years. During this time I suffered mentally, was put on anti-depressant medication, and attempted suicide – all due to family violence. It took me ten years to realize, and be strong enough, to extricate myself and my children. Then, finally in charge of my own life again, I studied to become a counselor/therapist and have worked in that field for 32 years. My specialism is suicide prevention. I chose life and made that life better. My hope is that my story will help others to choose life also.

Keywords

Suicidal ideation · Domestic violence · Suicide prevention and therapeutic intervention · Recovery

There are two parts to my story. One is my story, and what I learnt from reflecting on what happened to me, and how I recovered. The other is my story as a therapist working with suicidal clients, and what I have learnt from reflecting on that.

To get to the depths of despair, where in that moment suicide appears to be the only way out, is hard to understand if you haven't been in that position. How do you get to that point of absolute desperation? What can pull you back from the brink? How do you repair and recover and move on? This is my journey to desperation, suicide attempt, and back.

In the 1980s I was a normal, happy office worker. I married at 19. By 23 I had fallen in love with a coworker, despite my efforts to avoid this happening. This was a

Active Intentions, New Plymouth, New Zealand

massive turning-point in my life, and began the downward trend. It wasn't long before I left my marriage to move in with this person, and within a week, realized I had made a mistake. We lived in the country – idyllic but also isolated, which seemed nice at the time. Now I know no one can hear you scream. The mask of my new partner slipped in the first week of living together, away from the observation of others. Having some sort of disagreement, about what I can't recall, he grabbed my head and banged it against the wall six times. I tried to fight back, but that only made things worse. It is relevant to say here that my one attempt to physically fight back, failed. And I think that the message he took from that was that he could hit me and I wouldn't, couldn't, stop him and more importantly, I wouldn't leave. I should have left. However, I was in love for one thing, and for another, we both worked in the same place and I couldn't really see a way out at the time without losing face.

I can see now that a sort of grooming began, where everything was my fault, black was white not black, there was a right and wrong way to peel potatoes (his way was the right way, mine the wrong way), and if the oranges were sour that was my fault too. Domestic violence – what was that? I certainly didn't know. It did not have a high profile back in New Zealand in the 1970s. Looking back now I can see how I was brainwashed, bullied, and abused into believing this was all my own fault and well deserved.

Once on the way to work, something went wrong with our picking up of a neighbor's child, and he gave me a back-hander across the face. Another time when he punched me, I had to try and explain at work that we had been play fighting. You can't get a black eye from banging into a cupboard door. After I kept his dinner warm for hours one night when he was late home, he threw the whole lot at me, splitting my head open and leaving me crawling around on the floor cleaning up the blood and food and broken china while he went for a drive. I once had a carving knife thrown at me that embedded itself in the door inches from my head. All of this "punishment," seemed normal and deserved. I "made him do it."

It is all so obvious now, it is about bullying and it is about control. At the time, I was stuck and still in love and being told it was all my fault. He told me he could see in my eyes that I was "devious." It's relevant to mention that he had been arrested as a suspect in a crime involving a family member before I met him. I saw his behavior as a product of his own violent upbringing. Seeing him as a "victim" made me feel sorry for him. I wanted to rescue him and help him recover from this. Instead he perpetuated the generational family violence onto his own children. I had, in hindsight, been almost complicit with his excuse for his violence toward others. This is all relevant, because there is a pattern here with other domestic violence relationships. The ongoing violence physically, emotionally, and verbally, with insults and putdowns, took me to a desperate place where suicide was an option. My psyche was so badly damaged. My sense of self almost destroyed. After my unsuccessful attempt, I seemed to become a shadow of my former self, existing rather than living. The verbal abuse was like brainwashing. The same thing over and over again, repeated until I couldn't think straight. Until I was desperate for a reprieve. Ear bashing is a great description – it can seem like it's driving you mad, and maybe it was.

Looking back I am trying to imagine my state of mind. I had been hyperventilating. He ordered me to get up every morning to cook him eggs and bacon – one morning I passed out, falling on the floor. I was scared of him, he messed with my head until my self-esteem and confidence just dived right down. He was heartless and uncaring and abusive, then at times, funny, caring, and loving. I ended up at the Doctor and was put on anxiety medication. He was referred to a psychiatrist, who suggested he could be put on medication for the rest of his life to manage his behavior. Of course this didn't happen, and that was the last time we sought help. Isolation helps keep the secret. The neighbors aren't close enough to hear you scream. We were out one day, and he was playing his mind games, verbally abusing me. I had my anxiety medication with me. I went into the toilets nearby and swallowed a whole lot of them. I wanted him to feel something. Anything. Remorse, guilt, pain, sadness, regret. I had had enough and I wanted it to end. My death would be a lesson to him. Payback. Moments later, my rational brain kicked in. What was I doing? Sacrificing my life just in order to get my partner to feel some regret for treating me like he had. *Desperation, pain, hurt, damage to the psyche*. I managed to vomit up the medication. I went back outside. I told him what I had done. No reaction. Nothing changed. We just carried on. Soon I was really trapped, I was pregnant.

In the 10 years we had together, I think I must have become a sort of zombie, functioning on one level. Sometimes it was better than others, then at times it was a nightmare. There was no real way out of the trap, I thought. I had another child. He was the same with the children as he was with me. Swinging between kind and caring, and then ranting, irrational, and abusive. I was conditioned. My spirit subdued. By the time I woke up to the fact that it was more important to leave the relationship for the sake of the kids, than it was to try and retain the family unit for the sake of the kids, we were all traumatized. Trauma that would be far-reaching for us all. Back in the 1970s and 1980s, according to some of the research, it was better for the kids for the parents to stay together regardless. It also seemed to be what society required. Solo mothers were perceived to be the lowest of the low. I truly believed I was doing the right thing for my kids. And still in love. And weak, scared, demoralized, and controlled. However things were about to change.

This was when things got really, really bad. The beginning of the end. After 10 years. Something tipped my partner over the edge again. He had the matches and the can of petrol and the three of us lined up in front of him, and he threatened to set fire to the house. I tried to phone for help but he grabbed the phone off me and threw it at the wall. At some point he de-escalated. Normality returned, as it usually did, and then the whole cycle would begin again. Then our youngest son developed psychosomatic appendicitis. He was hospitalized after pain that had escalated suddenly and alarmingly. Incredible pain. Screaming from the child in pain and screaming from my partner that he was "just attention seeking." I was forbidden from sleeping with the child, and ordered back to our bed. The stay in hospital, which my Doctor ordered for mother and child, finally resulted in the secrets coming out. My son relished being in hospital and the symptoms disappeared. Like magic. The social worker, also a past victim of family violence, uncovered the problem.

That was huge for me. I realized I was not the only one who this had happened to and the abuse was not my fault. Normalizing of my situation by someone who had been treated similarly. I can't stress enough the vital importance of this empathic response from a fellow sufferer and the effect it had on my whole future. Understanding, empathy, genuine positive regard, nonjudgmental, non-blaming. Massive reality check for me. Our child was apparently terrified of his Dad. Terrified enough for his body to create a very painful way out. We ran away shortly after returning home. He had always said he would kill me if I left, and I was not fit to take care of the children and should be committed. I believed all this, as I was meant to. It kept me under his control. It helped keep me there. No longer.

This is the point for me where the journey back really began. I had no self-confidence and no self-esteem. I suffered from anxiety and depression. My ex, who after we split joined an anger management group, set me up with a male counselor from the group. Looking back on this now I think this was probably about maintaining some control over me. I was frozen and terrified of the male counselor because he was male. I was referred instead to a group for battered women. I started at the very bottom to begin regaining my self-esteem. There was a checklist. I can brush my teeth, I can drive a car. I was terrified of men. I couldn't get in a car with one I wasn't related to. I stuttered and had no confidence or self-esteem. At all. I was still being bullied by him, and I needed to get strong so I could stand against the behavior. I was out but I wasn't free.

Two years on I was a little stronger and I decided I wanted to help others. In 1988 I threw myself back into living instead of just existing. I joined Lifeline and began to train to become a counselor. I also volunteered at Budget Advisory Service and Victim Support. I enrolled in a Degree Program in Psychology, and enrolled in a Certificate in Counseling Course. During this time I was bringing my children up mostly on my own. I still had significant low self-esteem and I was frightened of most men. I began in the counseling courses, to gradually work through and understand that the domestic violence was not my fault. I was not the worst person in the world. I did not deserve to be treated like that. I wasn't responsible for my ex-partner's behavior. His behavior was his own choice. We make choices about how we behave. You choose to be violent, or you choose not to be violent.

I carried on gaining qualifications while counseling others. Unfortunately, my suicidal ideation continued after I left the relationship. It reoccurred when I was made redundant, when I read in the paper a very dear friend had suddenly passed away, and when I felt bullied and powerless at University. I believe that when you make an attempt at suicide you create a pathway in the brain, and when crises happen then that pathway, the suicidal ideation pathway, opens up again. It seems to me like you are now pre-programmed to consider suicide when something significant goes wrong. For myself it seemed to be when I was triggered into the past where my security and my sense of self was threatened. For example, I was made suddenly, and I thought illegally, redundant. I briefly considered suicide as an option. My rational brain, however, was functioning well enough to come up with more than one other solution by this time. Go to the bank and ask to have my mortgage payments frozen. The bank said no. My next option was to take my employer through a legal process.

Or suicide. I had to do the legal process in order to kill the suicidal thoughts. There was no other choice. I felt if I didn't stand up to this I would be bulldozed back into being a victim of violence. I don't think I would have survived that. Another time when suicide came to my mind was on hearing about the sudden loss of a dear friend. *Intense pain. Unbearable pain and loss.* I felt an overwhelming and impulsive urge to walk into the sea in order to have that last conversation with him. The intensity of this urge shook and surprised me. Again my rational brain jumped in. What if we did not end up in the same place on the other side? I found other ways to have that last conversation. Then again when I was in my last year of my study, I felt bullied by two tutors. This caused a huge amount of stress because it had catapulted me back into the same feelings I had in the domestic violence relationship. The trigger – black was not black but white. *Powerlessness.* However this time my body responded to my anxiety with a transient ischemic attack (TIA). My anxiety needed to be better self-managed and now I needed medication to avoid risk of stroke and heart attack. It was different this time though. I did not lose hope, I had a problem-solving strategy to deal with it. For once, suicide was not the first thought. I lodged a complaint. The helplessness and hopelessness was absent because I had a plan. And it wasn't a suicide plan this time. In hindsight, I was moving along on a continuum from suicide as a real option at one end, toward a point along the way where suicide was just a fleeting thought, whose influence is waning. Moving out of overwhelming emotions, to rational thought and on to problem solving, works for me. However I still have to do intensive cognitive work to contain the anxiety.

My journey of recovery took many years. My study and career played a huge part, by helping me find myself, and find my future. My life needed to be better than it had been. Hope is vital in recovery. I needed hope. Hope that I had a better future. I needed to recover. To change all the negative thinking, I had to change the tapes in my head. "You are not good enough. You will never be good enough. Everything you do is wrong. You should be locked up." I needed to believe I wasn't a bad person. I needed to believe I was worthy as a parent. I needed to prove I wasn't what I had been painted as. Nothing would have changed if I hadn't solved "the problem" by leaving the relationship. I firmly believe that we need to try and work out what is the cause of our depression, our anxiety, and our suicidal thoughts. That is, to my mind, where the change needs to happen. Choose life but make that life better. I had to believe life outside the relationship would be better. I had to first, leave the dangerous relationship, then start to find myself. The self I had lost through years and years of abuse. Not all suicides are about domestic violence, but many suicides are about loss of hope and damage to the psyche. No hope that things will get better. Pain. Intense pain that doesn't seem to let up. No light at the end of the tunnel. Hope may be there, but we can't see it, can't find it. Those of us in that place have a reason to die, we needed and all do need to find a reason to live. To find hope for a better future. And make that future happen. One small step at a time.

For me, and I found with others too, suicide was/is deeply personal. What may not seem enough of a reason to take one's life to others, may just be the last straw in a build-up of things that are causing pain for the at-risk person. While the causes of suicide are many and varied, we need to look below the surface to the effects, of what

is going on or has gone on in the environment, on the sufferer. The cause of my attempted suicide is the message I took for myself from what was happening/done to me. I was no good, worthless, at fault, scared, and a coward, and there was no possible life for me away from the relationship. I was in effect, painted into a corner where there was not only no way out, there was no glimmering of an option other than the one I came up with – suicide. Leaving became impossible – I would be followed, killed, and have my children taken away. It was then that I briefly considered homicide, after I had given up on the idea that fate was going to rescue me. I know this does not put me in a good light, but I am trying to highlight the desperation at that point that you consider anything. The last thing children need is one parent dead and the other in prison charged with murder. At that time I did not have the strength to contemplate escape, I was trapped, stuck. Endure.

I have found with many of my clients that there has been significant damage to the psyche at some time in their life. This has made it difficult for them to have the resilience to deal with crises when they occur. For example, “when did you first notice depression coming into your life?” I often ask. “When I was a child and I tried to kill myself,” was a not uncommon response. Follow-up question – “What was going on in your life at that time?” And the story follows. What comes out of these interactions is often the clue to some damage that has been done to the psyche. Something that was said to them that they are still carrying around. A negative message about themselves. Much like my negative messages that had damaged my psyche. Bullying causing fear, and feelings of not being good enough, not being loved, not being wanted. Valueless.

My aim, when dealing with suicidal ideation and depression, is to find out where, in a person’s story, that damage was done that might still be causing distress. What message about themselves they have taken from that event. Though we don’t know it at the time, this moment, or series of moments, can change our life. Often because we allow ourselves to be damaged by absorbing negative messages about ourselves. A personal message that is still with us. Still causing problems in our lives, often by diminishing our self-esteem, making us feel that we can’t achieve. Messages like “you are hopeless, you will never be any good.” These messages can come from people trying to hurt us or from thoughtless comments just thrown out without regard for the consequences. These messages can be given in moments of despair or wrongly used as motivators. However they often cut to the heart and do significant and long-lasting damage. The message that has followed us around, often since childhood, or for others like myself at a later age, can mean that we believe we are not ok, and will never be any good. *Worthless. Unlikeable.* A perpetuating cycle of self-blame and negative self-worth. A negative cycle. A low self-esteem can dictate the choices made throughout life. Maybe you don’t aim for the best in jobs, career, or relationships because you don’t think you are worth it. Maybe you rely on drugs, alcohol, gambling to either zone out life’s problems, or give you a lift. Then you have the problems you started with plus the things that often go along with alcohol, drugs etc. Addiction, loss of money, loss of cognition, loss of relationships, violence.

After years of failing at life, people can end up with no confidence, no self-esteem, and no tools to self-rescue. They may not be resilient to perceived threats to

the psyche and just sink lower. They may feel both helpless and hopeless and this is what can lead to suicidal ideation. Things will never get any better – there is no light at the end of the tunnel. To give up, to find a way out. To end the pain. It's like they have gone off on a side track instead of continuing on the main rail track, and have been stagnant or very limited in their progress. Getting them back onto the main trunk line means repairing damage and moving forward. Reframing. Rationalization. Reality Checks. Who would they have been if they hadn't been damaged, if their progress hadn't been stunted? Finding, recovering, repairing that person, their potential true self.

I often work from a perspective of situational analysis. "What did that person actually say?" "How did you take that message?" Or "what message did you take from that that you are still carrying around?" Often it is self-blame, we are good at that. If we turn it around and look at the behavior of the person who said whatever, we can see things from a different perspective. Instead of absorbing a comment from someone and using it to further beat ourselves up, letting the comment bounce off us limits the damage it can do to us. Looking rationally at this, what a person says to us can be about the other person having a bad day, or picking on us. It doesn't mean it's true or earned. We clutch it to us and it often dictates how we feel about ourselves for decades. We also assume we know what other people think about us. This is at best not possible, and at worst very damaging. We are not mind readers!! Don't even try!!! If you want to know ask, if not don't worry about it.

What can we do to help prevent suicide? Education for everybody on suicide prevention. Everybody needs to know what to do if they think someone is at-risk. There was a time when the word "suicide" was like a swear word. Many people thought, and maybe some still do, that if we mention suicide it will put someone at risk. About two thirds of health professionals in a workshop I attended once, struggled to actually ask "have you thought about suicide?" That was only in a role playing situation. We need to be brave enough to ask. Remember, it shouldn't be about our fear, it should be about the other person's well-being. Ten years ago I was in a Masters Level counseling course, with a mix of new and experienced therapists, and was castigated three times by tutors, for trying to introduce the subject of suicide. I was appalled. Again, everybody, especially therapists, but not just therapists, need to know what to do about suicide risk. Family members can be the ones who notice subtle clues. They need to know what to do to try and help that person. There is fear around talking about suicide. We do need to be careful how we talk about suicide. However we do all need to know what to do if we think someone is at-risk. We are TRYING to prevent suicide. Don't let your fear get in the way of possibly saving a life. However, it is always about the choice of the person at-risk at the end of the day. I advocate being aware of risk, listening, asking the person if they have thought about suicide, getting them help and keeping them safe. Some at-risk of suicide give no indication they are this troubled. We become very good actors. Others will drop a hint or a clue because they want someone to help. This may be something like saying they don't want to be here. It's important to ask "have you thought about suicide?" It's a hard question to ask. However if we don't ask we might miss an opportunity to help. If you get that chance, take it. Resist the

temptation to change the subject to something more comfortable for you. Listen, listen, listen!!

Safely talking about suicide. In New Zealand we do not publicize in the media how a completed suicide took their life. Reducing access to means is important. In New Zealand we have laws restricting firearms.

Children need to grow up to be resilient with good self-esteem and confidence. They need to be prepared to deal with difficulties in life. Anxiety seems a huge problem for young people. Teaching life skills in school is vital, I believe – the earlier the better. Learning how to deal with what makes us anxious. I believe that kids need survival skills. With suicide prevention, ideally we are dealing with early intervention from conception. Babies prior to birth know what kind of environment they are being born into. Violent, angry, calm, soothing. Parent education is needed to teach how to limit damage to children growing up and to give them skills that will prepare them better for life ahead. A family violence atmosphere can impact on children as much, if not more, as the impact on the adult victim. Perpetrators of family violence are also role-modeling to their children how to be in a relationship. How to treat a partner. They are normalizing violent behavior. Perpetuating cycles of violence. Again damage to the self-esteem and confidence from a violent upbringing or a neglectful upbringing. Children need to know they are loved by their parents and this tells children they are able to be loved by others. My evidence is practice-based. I see many people in their 20s, 30s, 40s, and older who suffered damage early in life, either in the home, bullying at school, etc., and are failing later on in life. Some of these people disclose the past suicide of a family member, and how that has impacted on them with serious loss and grief, and in some cases the suicide is role modeling a problem-solving strategy. Suicide is not the only option. Learn to come up with more than one response to situations.

Impulsive behavior can result in a suicide if a sudden crisis occurs where there is that loss of hope without rational thinking. Young men can act on impulse without thinking through the consequences of suicide. We can't come back from suicide. Teaching impulse control – maybe in schools. Problem-solving skills, maybe in schools. Or for parents to ensure these skills are taught. Resilience is vital to survival. Good self-esteem and self-confidence is vital. Whatever the intention of a put down, sometimes to motivate, sometimes to highlight bad behavior, it often causes damage that children may never recover from. We need to think before we speak, about the possible damage we can do with our thoughtless words. Insults do not motivate – they hurt, they damage, they linger. Think it, don't say it. Then think about what you can say that won't damage. Love the child, hate the behavior. It's the behavior you want to change.

I have now been working in suicide prevention for 32 years. In that time working with very many suicidal people. That may not be why they came for help, but the suicidal ideation can be just below the surface. I always contract with my clients to stay alive while we are working together. A commitment to life while we explore, repair, and work toward positive change.

In 2010 I wrote *“Survive and Thrive Choose Life, a handbook for those at risk and those who want to help.”* This incorporated some of what I had learnt about

preventing suicide. I am at present the New Zealand Representative to the International Association for Suicide Prevention (2017–2022). During the really down parts of my life, there appeared to be no hope for a better future, no escape from the nightmare. I might not have been alive today. I'm glad I am. It didn't happen overnight but it did happen. I made it happen, one small step at a time. My children and I broke the cycle of generational family violence and I'm immensely proud of that. I chose life and made that life better, hopefully my words will help others to choose life and make that life better for themselves.

Abstract

Suicide is a serious public health problem throughout the world. An interdisciplinary approach is needed to better understand and prevent suicide and life-threatening behaviors. Syndemic theory accounts for the role that culture plays in exacerbating risk factors that too often result in self-inflicted death. The culture of silo mentality in the suicidology community impedes significant progress in understanding and preventing suicide. This chapter outlines the use of syndemic theory in the study of suicide and introduces the concept of the anthropsy, which incorporates the framework on the psychological autopsy to research suicidality on a macro scale. A syndemic in the US Intermountain West is believed to be of syndemic origin. A review of an anthropsy informing this conclusion is made.

Keywords

Suicide · Syndemic · Anthropsy · Culture · Theory

Worldwide, there were over 793,000 suicide deaths in 2016 [74]. For every death it is estimated there are 20 suicide attempts [75]. There are numerous theoretical constructs that have served as a framework for explaining suicide and related phenomena. These theories have sprung from the disciplines of psychology, biology, and many other fields. When a significant problem is complex, it needs an organized means of inquiry, and is not easily explained by one approach; it necessitates an interdisciplinary approach [57].

The old adage is “it is tempting, if the only tool you have is a hammer, to treat everything as if it were a nail” ([40], p. 15). My fear – anecdotal as it may be – is that suicidologists gravitate towards their own academic disciplines in their approach to the study of suicide. As John Muir [45], the noted naturalist said, “When we try to pick out anything by itself, we find it hitched to everything else in the universe” (p. 10). The widely hailed founder of suicidology, Edwin Shneidman [60], famously said, “Suicide is everybody’s business” (p. 238) and advocated for a multifaceted approach to the study of suicide. The suicidology community would do well to consider both Muir and Shneidman’s assertions in tandem. It is my contention that syndemic theory is well suited to compliment, incorporate, and embrace theory from across the academic spectrum.

Culture

Before going any further, it is necessary to give a brief background on the term and culture and define what is being referred to as culture in this chapter. Culture is a concept originally developed by anthropologists, with the premise that it encompasses the features unique to a specific group of people, unaffected by the influence of others [36] – a rather dated idea when considering the impact of globalization.

Today, culture means different things to different people, with even anthropologists unable to agree on one universal definition (p. 44). Some scholars define culture as “things” that are impressed upon us as we grow up, such as manners or religion ([43], p. 2). Others define culture as the sum of a complex system of “knowledge, belief, arts, morals, law, custom, and any other capabilities and habits acquired” as a result of belonging to a particular society (Tyler 1871 as cited in [59], p. 40). Archeologists maintain that culture is reflected in artifacts produced [56] and food consumed by a specific group of people, which can be determined in a multitude of ways (pp. 163–192). Linguists assert that language is a part of culture and that we are limited in our understanding, perception, and interpretation of the world by the words and grammar of our respective languages. This language limitation is referred to as *linguistic determination* and is part of the well-known Sapir-Whorf hypothesis [24].

While categorizing people into social or cultural groups is common practice, a warning has been issued that such categorization may pose problematic when used for research purposes [26]. When considering cultural category, it is important to note that cultures vary by observer perspective, are often dictated by, and change throughout history, that individuals may move between categories, and that category sometimes interferes with the phenomenon being studied (pp. 392–397).

In the context of this chapter, we are defining the features of culture as:

- The sum of a complex system consisting of “knowledge, belief, arts, morals, law, custom, and any other capabilities and habits acquired” as a result of belonging to a particular society (Tyler 1871 as cited in [59], p. 40)
- Extending to language, dress, and dietary habits
- Includes thought patterns and reactions to stimuli
- Shared by the majority in a group of people
- Comprised of subcultures
- Dependent on the perspective of the observer and potentially obscured by the limits of one’s language, including jargon within a culture/subculture
- Malleable and dynamic in nature
- Having the capacity to influence, and be influenced by, other cultures
- Consisting of features that are not only impressed upon one growing up but shaped by experiences throughout the lifespan
- Subjectively determining what is normal versus deviant
- Possessing a unique discourse – written, spoken, and symbolic communication
- Social discord, expression of distress and eustress, and cultural sanctions on a given topic, like suicide [15]

My working definition is an attempt to get at the ethos of a given culture – the very essence, spirit, and character. Having said everything I have said about culture, I would like to caution that not learning from the historical missteps of the academics who established anthropology – for instance, that the shape, size, and features of a human skull are indicative of one’s level of intelligence – is a dangerous and downward spiraling effect that can truly hurt others [70]. Other hazards include

ethnocentrism – seeing our own culture as superior and the center of all perspectives, and not understanding cultural relativism – judging others by our own cultural standards [43].

Intersectionality

The term intersectionality is credited as originating in 1991 from the work of Kimberle Crenshaw [28, 49], who utilized it to acknowledge the fallacy of looking at oppression from one lens – racism or sexism – rather than both, as a more complex means of deconstructing identity politics [17]. As such, intersectionality is defined as belonging to one or more social identity construct (e.g., combinations of race, gender, mental health status, etc.) that results in complicated systems of concurrent or alternating privilege or oppression [28]. Intersectionality is an important consideration in the study of a phenomenon, like suicide, because not accounting for intersectionality in research draws on only one variable to the exclusion of others (p. 91) and “ignoring differences within groups contributes to tension among groups” ([17], p. 1242).

Because intersectionality entails multiple identities in a single person that are enmeshed with each other, teasing the issues out regarding these identities is important. Future research must also take into account the compounding effects of intersectionality. At present, there is significantly more research on the single identities of race/ethnicity and sex.

Syndemic Theory

Syndemic theory is of anthropological origin and advanced by Merrill Singer [67]. The word, “syndemic,” is a neologism that describes a synergistic epidemic. The theory asserts that a public health issue is the result of two or more physiological factors combined with a cultural factor [67]. Syndemic theory encompasses, compliments, and builds on the social determinates of health (SDH) theory and the bioecological theory of human development (BTHD).

The World Health Organization [76] defines SDH as:

... conditions in which people are born, grow, work, live, and age, and the wider set of forces and systems shaping the conditions of daily life. These forces and systems include economic policies and systems, development agendas, social norms, social policies and political systems.

SDH theory asserts that the aforementioned conditions and forces impact the health of individuals and communities.

Bronfenbrenner’s BTHD [10] posits that five systems, and individual characteristics and traits, interact to influence a particular person’s development. These systems are as follows:

- **Microsystem:** A series of interpersonal relations.
- **Mesosystem:** Influences from the interaction of two or more settings in which the individual is involved directly (e.g., home and work, school and home).
- **Exosystem:** Interactions between two or more settings, at least one of which does not usually involve the individual directly.
- **Macrosystem:** The overarching system comprised of all of the others within a cultural context.
- **Chronosystem:** Changes that are experienced over time.

The US Centers for Disease Control and Prevention (CDC, [72].) and the US Surgeon General and National Action Alliance [73] utilize a modified version of the BTHD as a framework for violence and suicide prevention.

As of this writing, syndemic theory has primarily been used to study sexually transmitted diseases [51, 66, 78] but has also been used, to a lesser extent, in the study of tuberculosis outbreaks [13, 54] and chronic disease conditions [50]. Research that employs syndemic theory to study suicide is limited, with the main focus being that of suicide among sexual minority men [20, 47] and suicide among people using opioids [51].

Culture and Suicide

While psychiatric issues undoubtedly play a significant role in the subjective ingredients resulting in suicide, it would be a mistake to only take pathology into account and not consider sociocultural factors [32, 33]. The much-touted statistic that 90% of suicide deaths are attributed to an underlying mental illness – popular even among the suicidology community – has a root in research utilizing the psychological autopsy as a means to retroactively determine if a victim had an undiagnosed mental health disorder [27, 34]. However, the psychological autopsy was designed as a tool to help the coroner assign a mode of death [64], and the purpose was never meant to retroactively diagnose mental illness and may be conducted by individuals who are not mental health clinicians [3]. Shneidman [61] contended that “The problem of suicide should never be addressed directly, phenomenologically, without the intervention of the often obfuscating variable of psychiatric disorder.”

A study conducted by the Centers for Disease Control and Prevention (CDC) epidemiologists revealed that 54% of Americans dying by suicide between 1999 and 2016 did not have a known psychiatric disorder [68]. Of course, the interplay between culture and mental health can have a negative or positive impact when it comes to suicide.

We know that certain types of suicide may have a predominantly – if not complete – cultural component. Examples include Durkheim’s [19] classification of suicide for altruistic reasons (e.g., the overly cliché throwing oneself on a grenade to save others), self-immolation among Tibetan monks [16], the practice of Sati [39], and the use of suicide as an atonement or restoration of honor in Japan [58].

Cultural Variations

When it comes to suicide, we know there are variations by culture, and researchers would do well to consider these differences in the greater context of the phenomenon. These variations occur in many different groups, including race and ethnicity [8, 21, 53], sex [46], sexual orientation [23, 31], mental health conditions [1, 14], and religion [25, 71].

Methodology in Research

To effectively grasp the complexities of syndemics and their constituent factors, methods must be employed that contribute to the epistemology of the phenomenon. Researchers must embrace a qualitative, quantitative, and mixed-method approach and come to the realization that one method does not best another.

Unfortunately, there is a prevailing attitude of intolerance towards qualitative research among quantitative researchers [22]. This belief in the superiority of quantitative over qualitative extends to the aristocracy of the suicidology community. The three leading suicidology journals have all demonstrated a consistent bias against the publication of qualitative research with a scant 2–10% acceptance rate [32]. This bias is myopic and forsakes the “why” of a given phenomenon, which is critical [42]. Conversely, not recognizing the important contributions of quantitative methodologies would be a commensurate mistake. The sage advice and observations of Shneidman [63] and Muir [45] call to the suicidology community. The question is will our community answer those calls, or continue our silo mentality, pitting psychology against clinical social work, social sciences against the hard sciences, qualitative against quantitative, clinicians against those with lived experience, and on and on? To be clear, silos do not damage the effort; however, silo mentality does [48]. A failure to engage in metacognition to change the prevailing culture among suicidologists will most certainly – and likely already has – cost lives. The proverbial hammer must be replaced with a multi-tool.

Syndemic Case Study

There are limited instances in which suicide has been studied from a syndemic perspective. The following is a summary of the research I conducted and will be highlighted as an example. Note this is but one way to employ syndemic theory and is not meant to be prescriptive by any means.

The Situation

The United States Intermountain West has an overall suicide rate markedly higher than the national average. The rates of suicide in the Intermountain US West are

correlated with high elevation [9, 18], even when sex, age, race, income, population density, and firearm versus non-firearm deaths are controlled [9]. Many theories existed as to why the rates were so high, including decreased oxygen levels as elevation increases. Critics posited that a false association (ecological fallacy) may be in operation [7]. There is a positive correlation between altitude and suicide rates [9, 18].

Location Details

Park County, Wyoming, was chosen as a study site because it had sufficiently high altitude, enough of a population base to interact with and observe the residents, and had a suicide rate of 40 per 100,000, compared to Wyoming at 20.4 and the United States at 12 [12]. In the study area, there is a lack of military bases and reservations nearby, and the population is 96.2% Caucasian, which limited confounding factors (p. 14). Cowboy culture was mentioned as a possible cause of a spike of suicides in Park County by the state suicide prevention coordinator [30]. The cowboy culture and the “cowboy-up” philosophy were also advanced as a significant risk factor on the State of Wyoming Suicide Prevention Plan [77].

Assessment

An ethnographic study was initiated in one county in the Intermountain West. Evidence-based suicide risk factors, as employed in the psychological autopsy technique [62], were used as a foundation to conduct a community-wide assessment for suicidality. This method is referred to as an anthropological biopsy or “anthropsy” for short. It should be noted that an autopsy occurs on nonliving organism, whereas a community is still “alive,” hence biopsy.

An ethnographic approach was employed. A total of 23 days was spent living in the study area, which consisted of participant observation, a series of semi-structured interviews (see Table 1) – with questions modeled after those contained in the

Table 1 Informants interviewed

psychological autopsy [2] – and keeping detailed field notes. This was supplemented by discreet photographic documentation of events and artifacts. Interviews were audio-recorded and transcribed. All data was uploaded to Atlas.ti qualitative analysis software for coding and theme recognition.

War Paths

The findings of the anthropy are as follows. Whereas psychological autopsies use the mnemonic, IS PATH WARM, the anthropy employs the use of WAR PATHS.

Withdrawal. Mental illness and associated stigma contribute to withdrawal from the community. Fear of bullying and being seen seeking mental health help may contribute to this. The spirit of independence may also enhance the effects. Traditional places of inclusion, like faith communities, become sites of denial and stigmatization, causing further withdrawal.

Anxiety. Increased by stigma and the perceived or real difficulty of accessing mental health services in a confidential manner.

Recklessness. Some residents engage in reckless behavior including substance abuse and driving while intoxicated, lack of concern for safety as evidenced by lack of helmet use, noncompliance with the seat belt law, and tobacco use. The subculture of the rodeo cowboy may include additional reckless behaviors, such as the risk of life and limb in rodeo events and a lifestyle that may encompass increased sexual promiscuity.

Purposelessness. The threat of the loss or diminishment of the cowboy identity. Perceived lack of usefulness of individuals to society, particularly among the elderly, who may see themselves as a burden.

Anger. This is fueled by substance abuse, the general sense of pessimism, and bullying among youth and adults. Nonheterosexual people are the frequent target of aggression.

Trapped. Limited opportunities for career growth or diversity and, to a lesser degree, availability of enough different leisure activities. Isolation also factors into the feeling of being trapped and may occur geographically, socially, and psychologically.

Hopelessness. Fostered by the feelings of pessimism about where the government, economy, and other issues considered important are headed. Isolation accentuates this and bullying behavior has a negative effect on hope.

Substance abuse. Particularly surrounding alcohol, prescription opioids, and nicotine. This includes the presence or absence of laws and regulations that are conducive to abuse, such as those that pertain to the high proof of alcohol available, no criminal penalties for serving the obviously intoxicated, etc. Altitude is known to amplify the effects of smoking and alcohol [55].

The Syndemic

Cowboy culture, combined with mental health issues and the effects of altitude, increase suicidality and likely result in a syndemic. See Fig. 1 for a visual of the

Fig. 1 Swiss cheese model applied to syndemic theory

findings. Additional anthropies need to be conducted in other Intermountain West areas to gather more evidence of a regional syndemic and to establish greater external validity.

Physiological Factor: High Altitude Effects

Imaging studies of pilots subjected routinely to extremely high altitude show a marked increase in white matter lesions in response to low-pressure environment exposure [41]. High altitude can cause dehydration, sleep disturbance, and cognitive disorientation. Those with respiratory and heart diseases may have their conditions exacerbated by altitude ([11]) and are at higher risk for suicide [6].

Physiological Factor: Psychiatric Disorders

Too often, society fails to understand that mental illness is a physical illness with physiological indicators and ramifications. In imaging studies of those with depression, lesions on the basolateral amygdala have been found to inhibit nerve cell generation [37]. Imaging has also identified white matter deficits in the brains of those with alcoholism that disrupt the limbic-prefrontal connections and results in emotional dysfunction [29].

In the course of my ethnographic research, I discovered evidence of pervasive substance use disorders (alcohol, opioids, and nicotine), anxiety (tied to pessimistic

discourse), and depression (secondary to bullying and isolation). Of course, altitude is known to foster and exacerbate paranoia, hostility, and depression [4].

Cultural Factor: Cowboy Culture

Wyoming is known as the Cowboy State and that ethos is blatantly obvious. Homann [35] defines several classifications of cowboy, and informants corroborated the existence of the system with a few modifications. These are the rancher/ranch hand cowboy, the rodeo cowboy, the movie star cowboy, and the “wannabe” cowboy. Regardless of whether or not residents identify with a particular type of cowboy, the residents – male and female – are influenced by, and are a part of, the cowboy culture. Residents of the Intermountain West appear to continue to be a suicide risk even when leaving their home regions to areas of lower altitude [65].

Swiss Cheese Model

Reason’s Swiss cheese model [53] is useful for visualizing the components of the syndemic uncovered in Park County, Wyoming. Figure 1 depicts the reciprocal relationship between the physiological and cultural contributors. The model draws an analogy between slices of Swiss cheese and a disastrous outcome. The central idea of this model is that removing one of the “slices” will prevent the calamity. This model has been used successfully in aviation and is widely hailed as the reason air travel is one of the safer modes of transportation [38].

Current Events and the Future

At the time of this writing, the world is in the grip of the novel coronavirus disease 2019 (COVID-19) pandemic. While it is too early to anticipate the effects of the pandemic on suicidal ideation, attempts, and deaths, it is known that mental health crisis agencies are experiencing markedly increased demand for their service by individuals whose mental health challenges are being exacerbated by COVID-19 [5]. The pandemic has become politically charged. Some people cite the scientific evidence and comply with public health requests and expect compliance by others, while others believe the pandemic is a human-initiated conspiracy and go as far as saying the pandemic is a hoax. Many others are on the spectrum between the two viewpoints. Regardless of the reality, culture is bearing heavily on the situation.

Simultaneously, civil unrest surrounding serious and social justice disparities, as a result of prolonged and pervasive systemic racism – and catalyzed by the police-caused death of George Floyd in Minneapolis – has sparked protests across the globe. The festering sores of a traumatic history Black people have experienced have been ripped wide open, and the full psychological toll is yet to be determined. The suicidology community is very concerned about increases in suicide and suicidal

behavior because of the many social and cultural factors in which this crisis is rooted [44, 69].

Suicidologists should study these current events and the implications on suicidality in the context of a syndemic, with the interplay of cultural factors thoroughly explored.

Summary

Suicide is a significant worldwide public health problem that demands an interdisciplinary approach. The consideration of culture and its interaction with other factors, viewed through the lenses of various professions and academic disciplines, is imperative.

Culture is made up of multiple components of beliefs, customs, and shared experiences of a group of society. There are many subcultures within a culture and people often belong to multiple groups, which is referred to as intersectionality.

Syndemic theory holds that an adverse outcome – like suicide – occurs as the result of two or more physiological conditions that are combined with cultural factors. Syndemic theory compliments other theoretical constructs. Researchers should embrace multiple methodologies and schools of thought and practice.

The powerful nature of culture in suicide has not been as fully appreciated as it should be, with assumptions of mental illness as the predominant root cause. It is known that suicide varies by culture and subculture. Qualitative research is more frequently employed in the study of culture. Because of an anti-qualitative bias, cultural anthropology is too often excluded from the body of knowledge – or at the least, suppressed. Qualitative and quantitative research can complement and support each other.

Syndemic theory has many applications. A case study was presented on a likely syndemic occurring in the US Intermountain West in an area disproportionately impacted by suicide. The cowboy culture of the US Intermountain West interacts with the physiological effects of altitude and pre-existing psychiatric conditions. This interaction is likely responsible for a large portion of the suicide deaths in the region. A Swiss cheese model of a syndemic may be a useful tool in preventing the adverse outcomes of syndemics.

The current pandemic and social unrest are syndemics in the making. Suicidologists would do well to research suicide and related phenomena related to this crisis in the context of a syndemic.

Abstract

The purpose of this study is to identify the suicide risk and protective factors among young adults from a cultural perspective, specifically Mexican women and men who have attempted suicide. Young adult population in Mexico has one with the highest suicide rates, 9.3 per 100 k inhabitants, and the suicide rate in Mexico is 5.4 per 100 k inhabitants.

Thirty-two young adults who had attempted suicide were interviewed. Participant's thoughts, feelings, actions, interactions, and circumstances around contemplating and attempting suicide were documented. A qualitative interpretive analysis based on the grounded theory was conducted. Eight categories were constructed which group and organize the participants' experiences regarding the causes, feelings, thoughts, actions, and circumstances related to suicide and suicide attempted.

e-mail: teremor@iteso.mx

The suicidal risk factors from the perspective developed in this study are mainly present in the family circle, characterized by a violent environment, lack of support, loneliness, precariousness, and silence. Under these family conditions, the persons at suicidal risk tend to establish an internal dialogue with themselves where their thoughts and feelings lead them to consider that there is no other way out, but to commit suicide. The community, comprised of the neighborhood, neighborhood associations, friends, school, and church, is an environment, poor in support resources, to which the participants do not usually turn. These social institutions do not offer accessible and timely support whenever the participants have resorted to them. The participants propose the following preventive measures: have a trustworthy person to be able to talk to about their situation, psychotherapeutic help, and family support.

Keywords

Suicide attempt · Domestic violence · Cultural factors · Young adult · Communication

Introduction

Suicide is an act in which the relationship of the subject, with his or her social surroundings, is expressed in multiple forms. From the perspective presented in this study, it is a cultural response to existential and vital problems. This response is diverse and varies from culture to culture. Even within the same culture, it can present variations according to financial, social, and political circumstances.

The International Association for Suicide Prevention (IASP) and the World Health Organization (WHO) sustain that suicide is preventable. In fact, the IASP affirms that every suicide is preventable. It is necessary to know the cultural conditions that enable the development of a suicidal behavior [1, 2].

Addressing suicide from a cultural perspective implies answering the following questions:

- What kind of communication interactions does the suicidal young adult establish within his or her family circle, community, and society?
- What are the conditions under which these communication interactions take place?
- For this population, how is suicide an alternative to dealing with their problems?

The aim is to answer these questions and retrieve the participants' subjective experiences regarding suicide. This involves reconstructing aspects in their everyday life that influence their decision to commit suicide.

It is crucial to explain concepts that can support the theoretical approach of suicide and suicide attempted in this study.

Theoretical Perspective: The Social Constructionism

According to Schütz [3], a social phenomenologist, the meaning of life is built around two basic elements: the *subjective meaning*, which corresponds to the processes that occur in the person's consciousness and create significance, and the *objective meaning*, which concerns the most broad contexts of meaning in culture and is shared socially.

The significance that grants meaning to reality is built in this psychocultural relationship, which happens between reality and the person itself. The language in this relationship is essential for it allows order and communication between the person's external and internal world.

This approach applies the way reality is known and built according to the concept of social constructionism [4].

A semi-structured interview was applied to gain access to the participants' subjectivity [5–8], as a tool to identify and understand the experiences and meanings of suicide and suicide attempted.

Methodology

The study's population was young adults from the city of Guadalajara, Mexico, since this group is among the population with the highest suicide rates in Mexico. The suicide rate in Mexico in 2017 was 5.4 per 100 k inhabitants and 9.3 per 100 k inhabitants in young adults between the ages of 18 and 45 years old [9, 10].

The suicide rate in the state of Jalisco in 2017 was 8.04 per 100 k inhabitants. Sixty-five percent of the people that committed suicide were between 18 and 45 years old [9, 10]. In this study, the age range of a young adult should be between 18 and 45 years old [11, 12].

The research method that was applied is the qualitative method based on the grounded theory [13, 16]. The instrument of research used was a semi-structured interview [5–8]. The participants were 32 people that had recently attempted suicide, 20 women and 12 men. The participants were self-aware individuals, with no psychotic disorders or addictions and have a monthly income between USD \$ 250 and \$ 500.

The participants were interviewed immediately after the suicide attempt, before any psychological intervention.

The interviews were held in mental health centers for people who had attempted suicide in the metropolitan area in Guadalajara, Jalisco, Mexico.

The following questions were asked during the interviews:

- What are the causes that make a person attempt suicide?
- What does a person who attempts suicide feel?
- What does a person who attempts suicide think?
- What does a person who attempts suicide do?
- What can be done to prevent suicide?

The questions were done in the same order while conducting the interviews, and relevant aspects from the participants' experiences pertaining to suicide and suicide attempted were explored.

All the interviews were recorded digitally (audio) and transcribed. Participants' identity has been protected through the use of pseudonyms.

Analysis Results: Categories and Subcategories

The identified categories and subcategories interrelate in a specific pattern that explains what goes on in the reality of a person with suicidal behavior. These are feelings, thoughts, actions, interactions, and circumstances that lead them to deal with their problems in a specific way.

Based on the data analysis, eight categories were constructed [13–16].

Resulting Categories

The different categories maintain a better identification in one of the three levels, although they keep a permanent interaction between them. (Source: author’s elaboration)

The categories are: (1) die, (2) feelings, (3) self-concept, (4) social support, (5) lack of love, (6) domestic violence, (7) precariousness, and (8) silence.

Below is a brief explanation of these categories and subcategories as well as bullet points exemplifying the categories.

The explanatory outlines are presented from the point of view of the person who has attempted suicide. They could explain what is happening in the person, his or her family environment, the community context, and the social context.

Die

For the participants the concept “to die” is a consequence of the relationships, mainly conflicting, violent, lacking support, or lacking communication, that the participants had established with people in their family, community, and social circles (Fig. 1).

They express their wish of death as “just die,” “rest,” “sleep,” “be done with problems,” “they will be better off without me,” “join a deceased relative,” and “ask for help.”

Even though the person expresses the wish to rest or stop suffering, the actual actions are targeted to end his or her own life.

Roque, a 19-year-old male, single. Additional information: None.

- **E:** The last push, what did you mean by that?
- **C:** *The end, death.*
- **E:** And, what else does someone feel? How does it feel right at that moment or before?

Fig. 1 Die: An intimate act, done in a conscious way and with a definite purpose: to terminate one’s own life. Total: 102 mentions. (Source: author’s elaboration)

- [...]
- **C:** *In finishing, the sooner, the better . . . , In doing things faster . . . to stop feeling all that I am feeling [17].*

Amalia, a 44-year-old female, single. Additional information: Sexually abused as a child.

- **E:** Do you have any other feelings, maybe in everyday life?
- **C:** *In the everyday life? Mmm.*
- **E:** Yes, every day.
- **C:** *In dying.*
- **E:** Do you think about it a lot?
- **C:** *Yes, yes, I do think about it a lot.*
- [...]
- **C:** *[...] well, not taking the medication, but there are a lot of ways to commit suicide. I think a lot about my sister, she has given me so much. I can kill myself, slit my wrists or many other ways. But I don't know, I don't even know what is stopping me, because I don't want to live anymore, I don't want to live [17].*

Rosa, a 24-year-old female, married. Additional information: High school education. First attempt.

- **C:** *[...] just that I was going to rest, I would forget everything, I wasn't going to go through everything I'm going through here, that they insult me and feeling bad.*
- [...]
- **C:** *Just rest and not having to be bother by anything, that no one tells me anything [...] [17].*

Carmen, a 39-year-old female, lives in domestic partnership with her second partner. Additional information: None.

- **C:** *[...] that nobody loves you, and well, you think that the door is the easiest way to go, and go like: "That's it. . . , that's enough, so many problems, I am going to solve them," and so you think that this is the best solution [...] [17].*

Martha, a 20-year-old female, single. Additional information: Living with her parents and siblings. Third attempt.

- **C:** *Sleep, That's what I wanted, but it wasn't possible.*
- **E:** Did you want to sleep for a while?
- **C:** *All my life [17].*

Francisco, a 25-year-old male, single. Additional information: Living with his parents and siblings, does not feel support from his family.

- **C:** [...] *mom told me that's it, that's enough . . . , that it was my fault, that I was the one that didn't want to be ok and that **she would rather see me hanging than having to hang herself for watching me**, and there, that's when I made my decision: "**You are right, I am useless**" and that is why I tried to commit suicide.*
- [...]
- **C:** [...] *I didn't want to keep on living; **I didn't want to be a burden to my family** [17].*

Ramón, a 23-year-old male, single. Additional information: He is homosexual, just ended his five-year homosexual relationship. He says his suicide attempt was a way to seek help.

- **C:** [...] *all I wanted was like, **give a red alter** to everyone, not so much as wanting to kill myself, but more of a: "**Help!**" [...] **I wanted to draw attention to myself**, I wanted to fill a void [17].*

Lilia, a 37-year-old female, divorced. Additional information: She lives with her mother. Her husband left her for another woman. She has two adolescent sons who live elsewhere because she cannot support them. She is in a relationship with a younger man who beats her.

- **C:** [...] *depression is what sometimes gets the best of me, it is the sadness. **It all comes together; is a whole package and it happens when everything crams in together and that's that** [17].*

The multiple meanings surrounding the fact of committing suicide indicate that in order to do it, the actual fact and its consequences are labeled other than death, such as *a better way of life for their relatives, that they will be better off when he/she is not around, or that the problems they are facing will be over once they put an end to their lives.*

Feelings

An emotional state is shaped around the decision to die, where the feelings the subject experiences do not help them find solutions or possible alternatives to their situation. These feelings feed themselves, together with the unfavorable circumstances in which they are submerged: domestic violence, lack of support, and lack of love, thus creating an emotional state pervaded by hopelessness (Fig. 2).

Culture determines the emotional repertoire of a society and provides that society with meanings, expectations, goals, interests, and values. Each culture defines a specific world; this is the result of certain preferences. The culture then tries to get each of its members emotionally conformed to the symbolic horizon built; this process lays roots in deep levels of the personality. Culture cannot be considered as an experimental science in search of law, but as an interpretative science in search of meaning [18].

Fig. 2 Feelings: A feeling appears related to a specific object or representation. A feeling is established on the subjective interpretation of an object's perception. Total: 229 mentions. (Source: author's elaboration)

The feelings expressed by the participants with suicide attempted were *loneliness*, *sadness*, *rage*, *despair*, *guilt*, *emptiness*, *fear*, and *anxiety*.

Loneliness

The term “loneliness” refers to a state in which a person feels alone, even though that person is not “necessarily alone.” This means that there are people who are in fact alone but do not feel lonely. It can be assumed that the frequency and quantity of the social relationships can help to avoid the feelings of loneliness; however, it is essential that these relationships are constructive.

Weiss [19] defines two different types of loneliness according to the sort of relationship an individual lacks: emotional loneliness, which results from the lack of a truly intimate tie or attachment to another person, and social loneliness, as the consequence of missing a network of social relationships [20].

Social norms state that, at each stage in life, it is “normal” to maintain certain relationships, such as having a group of friends, being married, or having a partner. Failure to meet these expectations can influence the experience of loneliness [21].

When asked the question about the causes that bring a person to commit suicide, Lourdes responded:

- **C:** [...] well, *loneliness* too... , *sadness* [17].

Martha, a 20-year-old female, single. Additional information: She lives with her parents and three siblings. There are six members in the family. This is her third suicide attempt.

- **E:** *So, what caused the second [suicide attempt]?*
- **C:** *Depression. **I was feeling alone**, I have always felt alone. Like, without affection, without love [...].*
- **E:** [...] *What do you think a person that attempts suicide feels?*
- **C:** ***A stone on the back, a huge burden, pain. That stone carries pain, disappointment, anguish, fears, horror. Just as if you were alone, bleeding to death** [17].*

Lilia, a 37-year-old female, divorced. Additional information: She lives with her mother. She is in a relationship with a young man who abuses and beats her. They both are substance abusers:

- **C:** [...] *Ever since my divorce, **I have been alone**, there is no one. **I do not have anyone's support**; I am just with my mom; I am living in her house [...].*
- [...]
- **C:** [...] *I am in my mom's house, **but I am alone**, sometimes I do not even get out of bed [...] **my loneliness is incredibly sad and uncomfortable** [17].*

Juan, a 25-year-old male, living in domestic partnership. Additional information: He claims to have relationship problems:

- **E:** [...] *what does someone who has tried to commit suicide feel?*
- **C:** *What do they feel? Well, stress. No. . . , well, **I felt alone** . . . , [...] *I wasn't in touch with my friends, or my parents. I don't even see my family anymore* [17].*

Agustin, a 42-year-old individual, married with children. Additional information: None.

- **C:** *Sadness, more than anything. **You feel alone, you don't feel people's support, not even from your family.***
- [...]
- **C:** [...] ***you feel loneliness**, even though you are spending time with them, but **within you, you feel this loneliness**, a void that you have to fill with your relatives or with your folks* [17].

Loneliness in people with suicidal behavior is a widespread experience that could be compensated to some extent through the family's support within suitable family relationships. This would mean a step further in preventing suicidal behaviors [21].

Rudd [22] validates the importance of family support when suicidal behavior arises. Usually people with suicidal behavior perceive an important level of support from their friends, not so much from their family members. The author interprets these results by stating that relationships among friends can never replace the need for family support; thus, despite all the support a person can receive from their friends, unwanted conducts will still develop.

Sadness

Sadness is a feeling that appears frequently among the feelings referred by the participants. It relates to personal and affective situations with their significant others, mainly relatives, partners, and friends.

For the participants there is no difference between depression and sadness. Depression is an emotional disorder with specific characteristics [23]; however, this study's individuals who attempted suicide use this term undifferentiated from sadness.

When posed with the question about the causes for suicide or what does a person that attempts suicide feel, some of the participants say they experience sadness.

Lourdes, a 38-year-old female, separated. Additional information: None.

- **C:** [...] *family problems... , conflicts... , and, hum, and... , and, well, loneliness too... , **sadness**.*
- [...]
- **C:** [...] *yes, **here in my chest. I feel, like... I have so much sadness** [...]* [17].

Lilia, a 37-year-old female, divorced. Additional information: None.

- **E:** [...] *What are the causes that a person tries to commit suicide?*
- **C:** *Well, it is so many things, but for me, **depression** is what gets the best of me. Sometimes it is the **sadness**. It all comes together; is a whole package and it happens when everything crams in together and that's that.*
- [...]
- **C:** [...] *an urge to cry, I don't get hungry, **I don't want anything, I don't want to go out, I am abandoned*** [17].

Claudia, an 18-year-old female, single. Additional information: None.

- **C:** [...] ***I feel lifeless** [...]* ***lifeless, tired*** [...] [17].

Roque, a 28-year-old male, single. Additional information: None.

- **C:** ***Feeling sad*** [17].

Patricia, a 22-year-old female, single. Additional information: None.

- **C:** *You don't feel anything, well, **incredibly sad**. An urge to run away from... , of just running away... , of getting out of this void that you feel. But it really **doesn't feel anything else, just sadness and despair, and this void*** [17].

Mario, an 18-year-old male, single. Additional information: High school degree. Diagnosed with depression.

- **C:** [...] *there are some days that I am super happy [...] and sometimes **I am sad**, and, well, **I cry** and all.*
- [...]
- **C:** [...] *I did let myself go, led by my feelings. I didn't think about anybody else.*
- [...]
- **C:** *Well, **depression, sadness** [17].*

Juana, a 40-year-old female, single. Additional information: High school degree.

- **C:** [...] *loneliness, Lack of love, **sadness**, feeling useless.*
- [...]
- **C:** ***Lots of sadness.***
- [...]
- **C:** [...] *I've gotten into **this sadness, into a depression** [...].*
- [...]
- **C:** [...] *it is rare when **I don't feel sad** [17].*

Lucia, a 19-year-old individual, single. Additional information: Diagnosed with depression. High school education.

- **C:** [...] ***sadness, most of all, sadness.** Nostalgia, self-loathing [...] feelings that things are not worth it and that you, certainly, are not worth it [...]* [17].

Rage

The rage that the participants express or feel is an emotion that has accumulated throughout the years. It relates to situations of rejection, the lack of support by significant members of their intimate or family circle, relationship problems with their partners, different forms of domestic violence, bullying, infidelity, financial problems, and unemployment. Sometimes rage arises from frustration from situations that are beyond their control, i.e., death or abandonment from their loved ones, breakups in relationships, neglect, and lack of care from family members, parents, children, and siblings.

Inés, a 27-year-old female, single. Additional information: Diagnosed with borderline personality and bipolar disorders. Second attempt.

- **C:** [...] *So, it's like... , the glass is filling up, filling up, with very simple stuff, and... , and the moment comes where... , the most simple thing, like a glance, a phrase, makes you lose it... , is... , is a time bomb, so, suicidal people, we are a time bomb.*
- [...]
- **C:** [...] *I did cut my arms with a razor blade [shows the scars], because **I was feeling so angry at myself** and **I just wanted to hurt myself**, I couldn't go back to the company [...]* [17].

Lilia, a 37-year-old female, divorced. Additional information: She is depressive. Abused by her partner. First attempt.

- **C:** [. . .] *a lot of rage and not thinking, because if you think, you don't do it. It's only a minute, if you are going to do it, do it or else just don't do it at all. I get so enraged by all that has happened to me* [17].

Mónica, a 25-year-old female, single. Additional information: Bachelor. Third attempt.

- **E:** And if you could like, describe, name those feelings that came over you: despair, emptiness, what else?
- **C:** *Despair, emptiness, **rage, rage with myself**, because I looked for to the easy way out; joy, because I was going to be reunited with the only family that ever truly loved me, my grandparents and my sister, who passed away* [17].

Ramón, a 23-year-old male, single. Additional information: Elementary education. First attempt. Homosexual.

- **C:** *So much frustration, it was like a domino effect of one feeling becoming another. I clung to my partner and to having him with me, then **anger and rage would hit me, because of what he was doing to me and I couldn't do anything to him**. Then the anguish by not knowing how to cope with my grief* [17].

Despair

Despair appears in situations that are impossible to modify, that are not accepted as they are, or that the individual would like to change, but it is not possible to do so.

Amalia, a 44-year-old female, single. Additional information: Elementary education. Sexually abused as a child. Second attempt.

- **C:** *Despair, because I want to get it quickly, not this time either. They took me to the clinic [the name of the clinic has been omitted], I only remember that I took the medication, that's as far as I remember* [17].

Miguel, a 39-year-old male, married. Additional information: Elementary education. Second attempt.

- **C:** *Oh!, it's so many things, uhm, it comes a time where you are overwhelmed by so much stuff; you **despair and more than anything, when you are full of doubts and you are about to lose your job**. You look for that way out, to die. I attempted suicide twice because of the **despair of not finding a way out*** [17].

Guilt

Guilt appears because the subject believes he or she has failed at some aspect in life.

José, a 23-year-old male, separated. Additional information: High school education. First attempt.

- **C:** *That's probably it. . . **Guilt** of not having done things. . . , things that could have been done better. So many things. . . of not having gotten to the point they did. . . That's it [17].*

Lilia, a 37-year-old female, divorced. Additional information: She suffers depression and domestic violence by her partner. First attempt.

- **C:** *[. . .] Well, yes, it hurts a lot. I remember everything and think "what for?" . . . , "why am I alive if I don't have them with me" [her children]. They are the only thing that I would want to fight for, but I feel so lonely. I **did make a lot of mistakes and now I am paying for them, I am paying for them in such terrible way** [17].*

Emptiness

Emptiness is another feeling that appears as part of the subjects' experience related to the suicide attempt.

Inés, a 27-year-old female, single. Additional information: Diagnosed with borderline personality and bipolar disorders. Second attempt.

- **C:** *I don't know, nothing fulfills you; not eating, not going out, not having someone say something nice, **nothing fulfills you. you feel . . . , alone. Like you have nothing, empty, sentimental emptiness, existential void, a void. You cannot fill it with anything, I tried to fill it with food. I used to eat so much, I would eat until I could not eat any more food and afterwards, I would vomit everything I ate. That's how I've been. . . , I've been like this for these past months. I didn't have this problem before but now I do, I eat until my stomach is like this** [makes a round figure on top of her stomach with her arms] **and I can't eat any more. My stomach and head ache from all the food I ate, and then I throw up everything. Then I feel terrible because I ate all that and then threw up, so it's emptiness. I think what I feel most of all is emptiness, and fear** [17].*

Ramón, a 23-year-old male, single. Additional information: Elementary education. First attempt. Homosexual:

- **C:** *I wanted to draw attention to myself, **fill a void.***
- **E:** *How long have you had this void?*
- **C:** *For the past 3 years [17].*

Fear

Fear is another feeling that several of the participants expressed.

Iván, a 26-year-old man, separated in the past 15 days. Additional information: Elementary education.

- **C:** *It's just that, since she left, I haven't been able to sleep. I just been crying. . . , fearing seeing her with another man [. . .] [17].*

Inés, a 27-year-old female, single. Additional information: Diagnosed with borderline personality and bipolar disorders. Second attempt.

- **C:** *I feel that everyone criticizes me., I hide from people. . . , from everyone. **I am afraid of people.** When I go to a very crowded place, I start having severe anxiety crisis, then. . . , I'm afraid of **going out, afraid of people, afraid of the street, that sort of things** [. . .] [17].*

Anxiety

Through anxiety expressions of Miguel, a 39-year-old male, we can identify an inner dialogue between his own ideas concerning his problems. He seems unable to stop it:

- **C:** *Well, every time I start thinking is about the same things, always the same things. I think about work, about debts. I sound like a broken record. I keep returning to the same things, but in negative way, I am all negative, negative. My wife tells me: - "You are inside [the hospital], I am outside, let me! But I know there is no money to pay, there will be no money" [. . .] [17].*

The difficulty of empathetically perceiving emotions relates more to a culture of emotional constriction rather than a culture of emotional expression; the latter is developed in countries and cultures with more democratic systems and horizontal authority structures [24]. The inability of family members to assume an emotionally closer role that promotes trust and communication and can sense the emotional needs of other members can be attributed to the fact that in the traditional Mexican family, these emotional communication abilities are not developed due to the fact that the strong family cohesion is bond together at the cost of individuals expressing their own ideas and feelings. Several authors name this way of interaction as "Familism"; this means that family assumes a predominant position in the social and personal life of its individuals, and it keeps the family's unity and integrity above the satisfaction of its member's personal needs [25–28].

Negative Self-Concept

A person's self-image can be a variable that influences his or her emotional well-being. Therefore, if the self-concept is negative, it is important to consider the possibility that the person might want to self-destruct or harm himself or herself [21] (Fig. 3).

The negative self-concept can be observed throughout all the participants' narrations. This is the result of interactions they have experienced with significant people in their lives, and these interactions can be classified as despise, disability, violence (in several forms), lack of care, and abandonment. The person's identity nucleus that Mead calls *the self* [29] is characterized by a negative self-concept in the participants. They tend to consider themselves as "a drag," "a failure," or "a disgust,"

Fig. 3 Negative self-concept: It is the mental image or perception that a person has of themselves. This is the result of what other people think of that person and how that person thinks about himself or herself. Total: 40 mentions. (Source: author's elaboration)

Katia, a 20-year-old female, married. Additional information: Elementary education. Second attempt. She lives with her parents and siblings in a household of seven. When asked what does a person who attempts suicide feel, she expresses the following:

- **C:** *Sadness, I just cry, I feel I am worthless. I tend to go looking for medications [17].*

Mario, an 18-year-old male, single. Additional information: High school education. First attempt. Diagnosed with depression. His brother committed suicide 3 years ago.

- **E:** [...] What does a person who attempts suicide feel? What do you have here? [The interviewer puts a hand to his heart].
- **C:** [...] *right now I feel like, I don't know. I feel like I am worthless, because I did cause my mom a lot of worries, to my dad and, well, to everyone who has come to visit me. I feel like a fool for having done this [17].*

Ramón, a 23-year-old male, single. Additional information: Homosexual. He lives with his parents and a brother. Just before his suicide attempt, he ended a relationship with his partner, a man several years older than him who supported him financially:

- **C:** *I think it is due to emotional instability, being so isolated from people. Overwhelmed with lack of time because of school, work, depression. A low self-esteem [17].*

Inés expresses the same feeling. She is a 27-year-old female, single. Additional information: She lives with her parents. Bachelor's degree. Second attempt.

- **C:** [...] *I am so angry at myself. You could even say that I hate myself, I totally hate myself and, my self-esteem is extremely low, so that results in me not wanting to be here anymore [her voice breaks one more time]. For me it is easier to hurt myself because I don't love myself. I don't accept myself; I don't like myself at all. I feel ugly, fat, stupid, and I am not really all those things, but I feel it so and believe it [17].*

It does not seem possible that a negative self-concept will spring in a person surrounded by a familiar and social environment that provides support and a positive image of himself or herself. The subject with a suicidal behavior tries to get out of his or her unhappiness by creating a mental deconstruction of reality, cognitive deconstruction. According to Baumeister [21], this mental stage favors disinhibition enabling the individual going from suicidal ideation to the actual suicide attempt.

Roque, a 28-year-old male, single. Additional information: Elementary education. Drug user. Lives with his parents. First attempt.

- **C: *Being a failure, a loser* . . . , *someone no one needs*** [here he pauses for seven seconds and then resumes], **scum** . . . [17].

The daily humiliation and despise that the participants with suicide attempted experience in their family environment condition the way they see themselves. The way other people look at them tells them they are worthless, they are despised, or they are humiliated by them. These other family members are their “mirror,” and as a result they convince and tell themselves: “I am a good-for-nothing,” “I am useless,” “nobody loves me,” “no one will care” [if they die], “I am worthless,” “I am scum.” In this sense, it is clear the essential role, in the ego’s configuration, the self-perception, and the self-worth, that interpersonal communication has.

Social Support

The studies measuring the connection between the social support perceived by the subject and the suicidal behavior lead us to the conclusion that the subject’s perception of his or her relationships, mainly those in the family circle, is an aspect to have in mind while studying suicidal tendencies. In general, suicidal people have a more negative perception of their families than nonsuicidal people. They also express to have less people whom to trust and from whom they could feel love and support (Fig. 4).

This lack of support leads them to feel hopelessness; they perceive themselves as incapable of solving their own problems. If they think that they are alone, and no one will help them, they feel as if there is no way out of the situation they are in, so they resort to suicide as a way of resolving their problems.

Martha, a 20-year-old female, single. Additional information: She lives with her parents and siblings. Lack of support can be identified in her expressions:

Fig. 4 Social support: Social support refers to the acceptance and availability for support from the family members, partner, peers, or institutions. Total: 26 mentions. (Source: author’s elaboration)

- **E:** What is the cause for this pain?
- **C:** *The people that surround you. **The very people around you are the ones that hurt you.***
- **E:** And how do they cause you pain?
- **C:** *In every way, talking behind your back, turning their backs on you, **not supporting you, ignoring you, letting you down, pretending, lying, so many ways** [17].*

Mónica, a 25-year-old female, single. Additional information: Bachelor. Lives with her father and siblings. Third attempt.

- **C:** *First of all, **having your family's support.** Make you feel like you exist, that you are not just part of the decoration [. . .] To feel part of the family. . . , **that they are with you, just plain and simple, and not because you started to grow older they ignore you. . . , a hug is always welcomed.** I haven't cried since I was ten years old, because **my mom used to say that crying was for the weak** [17].*

Rosa, a 24-year-old female, married. Additional information: High school education. First attempt. When questioned if she ever asked for help to solve her domestic abuse situation, she said no. The interviewer asked why. Her answer:

- **C:** *I don't know, out of neglect. I didn't find anywhere to go. I **thought I would be able to manage it on my own** [17].*

Juana, a 40-year-old female, single. Additional information: High school education. Second attempt.

- **C:** *Well, that **nobody cares about me, I do things to help others and I don't ever get a "thank you" back, I don't get anything back** [17].*

Carmen, a 39-year-old female, domestic cohabitation. Additional information: Bachelor. Second attempt.

- **C:** *Mi partner, my partner. . . , he makes me feel, makes me remember the past a lot and that traumatizes me. The past is past, right? and it can stay past. . . No, **my mother, of course not, she won't help me. No one has ever supported me, given me a hand, it's always been me, alone, since I was a child. There are problems that have no solution anymore, and well, that's what you do** [17].*

Social isolation plays a direct role in suicide. If social isolation is a primary condition in suicidal acts, to prevent these suicidal acts, the individual must have an appropriate interaction with meaningful personal relationships in his/her life [30].

Social support is crucial in people who have attempted suicide. The typical family of a person with suicidal behavior conducts themselves in a very particular way. The familial environment is full of relationship problems, interpersonal conflicts, anger,

ambivalences, rejections, and communication difficulties besides a myriad of stressful events [21].

Prior to a suicide attempt, people with suicidal behavior have an intrapersonal communication, i.e., a dialogue with themselves. Difficulty to express and effectively communicate their problems and feelings leads people with suicide attempt to live in emotional isolation. Communication is executed among one's own feelings, emotions, and thoughts, in an enclosed and circular feedback. Some of the participants claim to have stated their intention to kill themselves as a cry for help; however, they did not get the response they were hoping for. This lack of support leads them to believe that no one will help them and that there is no other way out other than suicide.

Lack of Love

Love is important for this study since its absence creates the feeling of being away from others. The subject experiences emptiness and isolation; for some people this causes emotional suffering, while for others it can be an unbearable experience (Fig. 5).

The kind of love expected from the other person, such as a partner, father, mother, son, or daughter, is a love that supports, accompanies, cares, understands. . . It is an unconditional and total kind of love.

Martha, a 20-year-old female, single. Additional information: She lives with her parents and siblings. Third attempt.

- **E:** What made you stay with him [her boyfriend]?
- **C:** *Love, because **when you love someone, you love them as they are, faults and all, as they say. I felt I could change those faults, but I was wrong, I couldn't change them, I will never be able to change them, that's how he is*** [17].

When Martha is faced with the question of the causes that make a person attempt suicide she responds:

- **C:** *Because no one pays them attention, because people despise them. **Because they show no love, not one detail and I don't mean financially, but a small detail; a snuggle, an embrace, an "I love you", I don't know, just anything.***
- [...]

Fig. 5 Lack of love: Lack of love is the inability to be intimate with another person while maintaining one's integrity. Total: 77 mentions. (Source: author's elaboration)

- **E:** And that feeling has prevailed until now. . . do you believe this has affected your decision?
- **C:** *I think so, it was like everything came, everything, everything just came: the grudges, the hatred, **the love that could have been at that moment**, everything appeared in that instant [17].*

“Lack of love” is the absence of communication, affection, and care. People with suicide attempted suffer from their partner’s violence, infidelity, several kinds of abuse, and other problems. However, their attachment to the partner prevents them from getting away from the relationship. The participants mentioned suicide attempt as a strategy to make their partners reconsider, thus tying this answer to the one that considers suicide as a solution to the person’s problems.

Some participant’s relationships are what Márquez [31] calls “unbreakable couples.” The unbreakable couple has a pathological dynamic, being this dynamic so rigid that it is impossible for them to operate in a different way; when the couple is together, they are in a permanent conflict, but when they are apart, they cannot work the separation out and seek to go back to the relationship in spite of the conflict [31].

Domestic Violence

Interpersonal violence is expressed in two forms: violence within the family or to an intimate partner. Interpersonal violence is also known as domestic violence; it takes place usually, but not exclusively, at home and among family members or with an intimate partner (Fig. 6).

Violence can be physical, sexual, or psychological or due to abandonment or deprivation. The environment where these violent acts happen as well as the relationship between the perpetrator and the victim must be taken in account [32, 33]:

- Psychoemotional violence:* This is the most frequent kind of violence. It is performed through acts or omissions that involve prohibitions, coercions, restrictions, intimidation, threats, demeaning attitudes, abandonment, insults, mockery, silence, and aggressive gestures. This kind of hostile behaviors tend to humiliate, offend, frighten, and have serious repercussions on a person’s security, self-esteem, and emotional stability [34].

Fig. 6 Domestic violence: Domestic violence is constructed by abusive behavior, both physical and emotional, that breaks the coexistence rules and affects the physical and mental integrity of the family members. Total: 100 mentions. (Source: author’s elaboration)

Martha, a 20-year-old female, single. Additional information: She lives with her parents and siblings. Third attempt.

- **C:** *So, we crashed, and he stepped on the gas and, hum. . . , and I was running behind him with my brother tagging along and he left us there. He sped up [the car].*
- [. . .]
- **C:** *A lot, because it's not the first time that he leaves me there, he just dumps me, it's been more than a few times that he just leaves me alone.*
- [. . .]
- **C:** *Uh-huh. Yes, he humiliates me, he shouts at me, he tells me nasty stuff.*
- [. . .]
- **C:** *Well, he tells me that I am a whore, that I am a slut, a tease, all those things [17].*

Katia, a 20-year-old female, married. Additional information: Elementary education. She lives with her husband and children. Second attempt.

- **C:** *I couldn't go out; he wouldn't let me go out. I had to be locked in, but he could go out with his friends. He would get home around four o'clock in the morning. He wouldn't let me visit my family, if I would go visit them, he would show up and get me out, furious. He said I had no business there. When I got out of work he was already dialing [calling on the phone], he would tell me he wasn't feeling right, that he had a headache or that I should take him to the doctor [Social Security medical assistance] [17].*

People with suicide attempted have a limited ability to express their feelings and regulate their emotions. Usually before the suicide attempt, they have had extended periods of emotional weariness due to conflictive situations, bullying, abuse, and violence.

- **C:** *Well, I am telling you, he is home three days and gone three days. He says he is going to work and that his workplace is too far away [sic] and blah, blah, blah, that kind of thing. . . And then, he just works and works but he never gets paid. . . [Keeps silent for a moment and when she speaks again her voice starts breaking]. What do you think would happen if I went to work and wouldn't get paid. . . well. . . , I don't show up Monday, don't you think? But he works and works and never has a dime. . . , and this woman sends me texts saying he bought her this and that, and he did this, and this to her, and so on.*
- [. . .]
- **C:** *[. . .] it's not fair, what he is doing to me. . . , I've never disrespected him. . . , ever. . . , His mom and dad say that I have taken so much crap from him, that they don't know how I do it. . . , I honestly don't know how I do it. . . , and his parents help me [17].*

Physical violence: This is committed directly against a person's body. It is an intentional use of physical force or power that harms the physical integrity of a person. This kind of abuse can cause injuries such as traumatism, bruises, cuts, burns, or fractures, among others. It is any act that inflicts nonaccidental damage by use of physical force or some kind of weapon or object, which either results in or has a high likelihood of resulting in injury, or physical harm, may it be internal, external, or both [34].

Violence, abuse, and abandonment within the family or intimate partner are hard to identify since the victims hide their situation out of fear to the attacker or because of the social stigma that this implies. Domestic violence is usually kept hidden and silenced. Both men and women can experience domestic violence from their partners, parents, or siblings.

In societies with stereotyped and rigid gender roles, such as those in Mexican society, the role a woman has in fact enabled the naturalization of violence, since women tend to suppress these violent situations [35].

Rosa, a 24-year-old female, married. Additional information: High school education. Lives with her partner who beats her. First attempt.

- **E:** What kind of feelings did you experience?
- **C:** *It was horrible, I didn't feel any support. My husband was doing his own thing, but I couldn't do anything. Just because **he is a man, he could go out but not me. Stuff like that.***
- [...]
 - **E:** Were you thinking on that option several times?
 - **C:** *Yes, every time I'd fite [sic] with him, when my children would see what he did to me. **Even if I wanted to defend myself I couldn't, I was so tired. He beat me like he hadn't beat me before***
 - **E:** When did he beat you?
 - **C:** *Yesterday* [17].

The facts related to domestic violence behavior in couples have similarities all over the world. Some of these facts are disobedience or arguments with the male partner, questioning the male about money or female friends, not having meals ready on time, ignoring the caring of the home or children, refusing to maintain sexual intercourse, and the male being suspicious of the woman's infidelity [34].

In some cases, the suicide attempt is preceded by a violent incident, making suicide a legitimate way to get out of a situation that they seem incapable of solving otherwise.

Lilia, a 37-year-old female, divorced. Additional information: She suffers depression and domestic violence by her partner. First attempt.

- **C:** [...] *I was laying facing down, suddenly he got on the bed, **grabbed my foot by the ankle, and just like when you crack the chicken's lucky bone, he broke my ankle. The other foot too. Maybe but just the nerve over here, he pulled it. It was***

a terrible pain, I couldn't get up, so bad was the pain. Not happy with all he had done, he grabbed a pair of scissors, those industrial ones that they use to cut wire, with a little hook, and he cut me here [pointed to her back] and that was also what made me do it [attempting suicide].

- [...]
 - **C:** [...] *He is a good person but he's very explosive, he gets mad at everything and ¡boom! Not me, I'm very relaxed, although lately I wouldn't take it anymore. Once he did beat me so bad that all this was black, I had all this area of my body black, my bone was sticking up [...] [17].*

Rosa, a 24-year-old female, married. Additional information: High school education. First attempt.

- **C:** *Because regardless of the way he is [beats her] I wouldn't like to see him locked up or anything like that, it feels terrible. I do love him, I don't know how I can love someone that treats me in such a way, but I do [17].*

Sexual violence: Any degrading action to the victim's sexuality that poses a threat to that person's sexual freedom and physical integrity. It is an abuse of power where the other person is considered an object to satisfy the aggressor's desires [34].

Amalia, a 44-year-old female, single. Additional information: Elementary studies. Sexual abuse background.

- **E:** What don't you like about your life?
- **C:** *Nothing, nothing, I don't like it, I don't find life interesting.*
- **E:** Since when you don't find it interesting?
- **C:** *Many years now.*
- **E:** How did you started to find it uninteresting?
- **C:** *Probably since my parents died. That was a long time ago, it has been like fifteen years since they died. I kept on living and all. People used to tell me to get myself a partner, that I should settle down and start a home, but I didn't find that interesting either.*
- **E:** Why didn't you find that interesting?
- **C:** *Because, as a child, three different man abused me, and so... , no [17].*

Mónica, a 25-year-old female, single. Additional information: Bachelor. Third attempt.

- **C:** [...] *when they explained it to me, I was in high school. We studied science books, anatomy, and all. They were explaining and I made the connections... Well, what they tried to do was rape me.*
- [...]
 - **C:** *It was an attempt [rape]. I told my mom: "Why, why didn't you say anything? You knew! I did tell you". [The mother answers:] "Oh, why would you want me to*

*say anything?, Do you want your dad to go to jail or what?, so **just keep your mouth shut, and don't say anything at all**".*

- [...]
 - **C:** *No, it wasn't my dad, **it was a nephew of an aunt by marriage**. But I told my mother and she would tell me: "Why would you want to say anything? **It's over! keep your mouth shut already**". And I was like. . . , **we are all afraid of mother** [...] [17].*

In this study, to die by suicide is a decision that is made because of living in a continuous abusive and violent situation. Men and women with suicide attempt experience violence in diverse ways; women experience more physical, psychoemotional, and sexual violence, and men usually refer to a psychoemotional violence. Physical violence refers to punches or beating that causes physical harm. Psychoemotional violence referred to, but not limited to, insults, threats, intimidation, or infidelity. Sexual violence refers to being forced into some form of sexual encounter using physical strength or threats without the consent of the person suffering violence [36].

The parenting patterns in families with domestic violence in Mexico are kept extremely differentiated for men and women, reinforcing the expectations for each sex; men are to be aggressive, showing strength and determination, while women must be docile, submissive, and obedient. These parenting patterns, as well as the bonds established within the family circle, affect the family dynamics, behaviors, subjective needs, and emotional displays. If and when the partner or the parents make use of violence, the resulting fear is not only toward the aggression itself but also to the possibility of a breakdown in the relationship, making them stay in a destructive relationship out of need of affection or sense of security and because they see and experience these patterns as something "normal."

Physical, emotional, sexual, and financial violence, combined with abuse, generate a violent family environment characterized by an excess of intense emotions: hostility, intolerance, hatred, and resentment, causing stupor, surprise, feelings of pain, and injustice in the members of the family. These various forms of violence inhibit in both the attacker and the victim the free circulation of affection, tenderness, and care toward the family members [37].

Precariousness

The living environment of the participants with suicide attempt displays various aspects of precariousness. This precariousness, in some cases, is due to the lack of employment and financial dependence to another person, such as a partner, father, mother, brother, or sister. The lack of financial resources and/or employment makes it difficult for the participants to improve their relationships and material circumstances. The financial situation affects the providing role, mainly of the male participants, and leads them to consider themselves as a burden to the family, increasing the risk of considering suicide as a way out [38] (Fig. 7).

Some participants referred experiencing a precarious financial situation; this could be considered a suicidal risk factor when paired with other circumstances in

Fig. 7 Precariousness: Precariousness refers to an insufficiency in resource to adequately satisfy the daily needs. It denotes a general condition of vulnerability, displacement, and insecurity. Total: 47 mentions. (Source: author's elaboration)

their personal and family environment. The participants that have a financial dependency feel trapped by their situation causing them stress.

Regarding financial independence, men seem to be more affected than women by unemployment. In 11 out of 12 cases, men mention unemployment or financial difficulties as a factor.

Ramón, 23-year-old male, single. Additional information: Elementary education. Homosexual. First attempt. He refers to economic problems due to a financial dependency to his partner. Ending this relationship implies financial difficulties.

- **C:** *I was in a five-year relationship with my ex-partner until yesterday, I was the one that made the decision of living this person's home. **The idea was to remain roommates**, but I couldn't stand it. I had to go through my grief. **I was very dependent on him, emotionally and financially** [...].*
- [...]
- **C:** *I wouldn't consider **the financial issue** as a problem, **but it did have an impact**, I felt pressured, that I couldn't manage my own finances, because **I had to pay debts, pay some things that I owe at school** [17].*

Mónica, a 25-year-old female, single. Additional information: Bachelor. Lives with her father and two siblings. Third attempt.

- **C:** [...] ***I just lost my job**, last May, and... **last night my dad called me: "Parasite, stupid"**, all the names you can think of... **he kicked me out of the house** [...].*
- [...]
- **C:** [...] ***"[her father's words] What is your contribution to the house? Tell me, what is your contribution?"** [...].*
- [...]
- **C:** [...] ***"U". says [her friend's name was omitted]: "Let's go to my place", That would be lovely, for god's sakes, I don't have a job. I don't have an income. There are seven people living at her place. That is totally out of the question!** [17].*

Roque, a 28-year-old male, single. Additional information: Elementary education. Drug user. First attempt. Lives with his parents. Unemployed. He refers to himself as a loser since he is unsuccessful workwise.

- **C:** *Not being able to be up to the expectations. . . , not being able to do what you must do . . . , nothing ever comes out right, you are always going back to the same place. . .*
- **E:** So, what would be “being up to the expectations”?
- **C:** *Being up to the expectations is like. . . , do what you must do, regardless if it’s work related or anything at all, it just must be successful [17].*

Miguel, a 39-year-old male, married. Additional information: Elementary education. Second attempt.

- **C:** [. . .] *I was thinking that I am worthless. I was thinking what’s the point, like: “No, life is not worth it and I am fed up”, and: “I have no job and I can’t figure out how to get my kids ahead in life”, like: “I am broke”, and also thinking that I was tired [17].*

In a situation like this, being the man and not being the provider affects the relationship with their partner.

Silence

Communication is a preventing measure for people with suicide attempted is what participants mention the most; being able to communicate what is happening to them and having someone they can talk to can help these people find other ways to cope with their situation. It can be a therapist or some other mental health professional (Fig. 8).

When the participants were inquired about the causes for attempting suicide, they frequently refer to family problems and lack of communication among them. Silence is a way of not “confronting” problems. Not expressing their feelings or acknowledging their importance is a constant factor. This kind of silence can be found at various levels: individual, family, community, and social.

José, a 23-year-old male, separated. Additional information: Junior high school education. First attempt. His answer to the causes for attempting suicide.

- **C:** *In my family probably the lack of communication, I think. . . . Within a person. . . . With the family members. . . , lack of communication [17].*

Fig. 8 Silence: Silence refers to not speaking about certain subjects, such as suicide and suicide attempted. It refers to the fact that, in an attempt to turn these troubling realities invisible, people avoid talking about them. Total: 56 mentions. (Source: author’s elaboration)

María, a 32-year-old female, divorced. Additional information: Bachelor's degree. Diagnosed with borderline personality disorder. Twelve attempts.

- **C:** *Healthy relationships, and a better. . . , a better structure. . . , or how can I put it? Structure, no, more like a better methodology to treat it [suicide]. I have been very consistent taking my medication, but. . . , **you always need it. . . , the psychological help and the family's support** [17].*

Isabel, a 27-year-old female, domestic cohabitation. Additional information: Elementary education. Suffers domestic violence:

- **C:** *Well, **solving problems better, talking.***
- *[. . .]*
- **E:** *What's another way to fix it?*
- **C:** *Well, now that I think of it, **going to a psychologist** [17].*

Rosa, a 24-year-old female, married. Additional information: High school education. First attempt.

- **C:** ***Ask for help, talk about it, let it out** . I always used to say: “I am going to a psychologist”, but I never did. **Maybe, if I had, I wouldn't be going through this** [17].*

Flor, a 38-year-old female, married. Additional information: High school education. First attempt.

- **C:** ***With therapy**, but I only went once. I got into a program that helps people with drug problems. On top of everything, my son became a dealer. But you **need to look for help** [17].*

Patricia, a 22-year-old female, single. Additional information: Bachelor. Second attempt.

- **C:** *I don't know. . . , **listen to people** I don't know. . . , try and **understand them, hear them**, not meddle in their lives. Hear them **without judging**.*
- *[. . .] also, I think **there should be subjects that talk about this, about when you are feeling sad and can't find the way out of your problems**, I think there should be subjects in school that help you detect when a classmate is having a hard time or when you see that things are wrong. . . . I think there **should be more information about it** [17].*

Agustín, a 42-year-old male, married. Additional information: Diagnosed with depression. Fourth attempt.

- **C:** [. . .] *sometimes it's also **lack of communication** . . . , **lack of communication**. And I truly, truly, truly, think it is all this depression thing, and getting this far are symptoms and red alerts we all have [. . .]* [17]

Ramón, a 23-year-old male, single. Additional information: Elementary education. Homosexual. First attempt.

- **C:** *Not being alone, having **one person, at least, that you can talk to**, or at least **espres** [express] everything you are going through now* [17].

In some cases, silence hides a violent environment that is rarely spoken about, since it is a social taboo as well as the embarrassment caused by accepting being a victim of violence [37]. When bullied, victims do not report or ask for help.

In some other cases, silence is the way to cover up what is going on. The silence “isolates” and “protects” persons from being vulnerable when they think other people know about their situation or their incapability to solve their problems leading them to the desire to commit suicide. Social silence toward suicide makes it evident that the State has no answers for this problem.

Discussion

Participants in this study have experienced daily conflictive relationships, mistreat, abuse, and violence. At some point in their lives, a critical situation develops: a breakup, a beating, the loss of a job, or a severe family conflict; this is when suicide is regarded as a way out.

Overwhelming feelings prevent the participants from thinking clearly, feelings like loneliness, sadness, anger, fear, anxiety, blame, and despair. The subjects maintain an internal dialogue with themselves; this dialogue validates the thoughts and ideas resulting from these feelings. According to the Interpersonal Theory of Suicide (ITS) [39], the capability to engage in suicidal behavior is a process separate from the desire to engage in suicidal behavior. The desire itself is not enough to commit suicide, because suicide is not an easy thing to do. According to this theory, to be able to go through with suicide, individuals must lose some of the fears associated with suicidal behavior. These fears are gradually shed by being continuously exposed to situations of physical and emotional pain, like domestic violence situations where the person becomes increasingly tolerant to pain, in both quantity and intensity.

The individuals keep their emotions to themselves; they do not talk to anyone about what they are going through, even when they are suffering or experiencing severe psychological pain. They pretend that “everything is fine” or that “this is transitory,” “I will get out of this myself,” “it is a matter of will,” or “this is a matter of time.” The participants in this study live in a violent environment that remains

unseen, and the topic remains unspoken, either because it is a social taboo, because they are embarrassed to admit being a victim of violence, or because they do not know how to solve their problems and then wish to be dead [37].

The participants' low self-esteem made them consider themselves *uncapable*, *worthless*, *good for nothing*, *a drag*, or *scum* and that *their family or partner will be better off without them*. The Interpersonal Theory of Suicide [39] proposes that the simultaneous presence of three common elements, family conflicts, unemployment, and physical illness, highly increases the probability that a person will develop a perception of being a burden to his or her family.

The support that participants get from their families is either scarce or nonexistent or is totally inadequate for their current circumstances. They do not perceive any possibility of support from groups in their community or social institutions. Some have sought help from public entities, but do not obtain it in a timely manner.

They experience hardly any love from their relatives and close people; they call this experience "Lack of love."

Domestic violence is common among both women and men. Women suffer psychoemotional, physical, and sexual violence, while men suffer psychoemotional violence.

The participants live in a precarious financial situation which affects other areas in their lives, limiting their possibilities to satisfactorily solve their needs within the critical situation they are immersed in.

Not expressing feelings in the relationships of a person – individual, community, and social – relates to individual hardships and the way to cope with that person's feelings, sometimes by remaining silent since it is the only known cultural way. There is a lack of knowledge on how to adequately address the emotional and affectionate needs of the family members; this creates an unpropitious environment for expressing emotions and feelings [40], moreover if the expression of such emotions and feelings threatens family unity.

This cultural assessment shows that people in suicidal risk have no relevant information that would lead them to seek help. Silence is present in all levels from individual to social. This kind of environment enables a higher probability of suicide and suicide attempt than one with higher levels of communication and trust within the family would [41].

Conclusions of This Study

A superior category "emotional closeness in the family" can be drawn from grouping family support, family affection, partner support, childcare, and family communication. As mentioned above, conflicts and problems within the family and couple relationships are the main causes for suicide.

A preventive measure to avert a person from attempting suicide is closeness and emotional stability as a solution toward family problems [42]. Having someone to talk to, either a health professional or a confidant, can prevent suicidal behavior [43], as well as favoring communication and the act of listening. Then we can confirm the

need to implement intervention programs that should be available and within the population's reach, so everyone throughout the nation can benefit from them.

The parenting style in Mexican men and women has certain characteristics that enable the normalization of violence. Some of these characteristics are expressions of socially deep-rooted cultural beliefs of what is considered appropriate for men and women [35].

From childhood, the education of Mexican and Latin American women is based on the value of personal sacrifice for the family as something positive and desirable, particularly when family cohesion is at risk [44]. Traditional women's role of subjugation is a normal practice in gender relationships: They are not allowed to have an opinion, to decide over their own lives, to decide if they want to work or not, to decide if they want to have sexual relations or not, or to decide who their friends are [45, 46].

These behaviors are accepted and reproduced by institutions such as family, school, and media. These are the socially accepted models and conducts for "femininity" and "masculinity." In addition, Mexican broadcasters widely transmit these models. Women are presented as good, sensible, and chaste [47]. Heroines are weak and dependent, and they are energetic and fight to defend their children, parents, or beloved one from adversity. The censoring of certain undesirable behaviors is done by the attribution of those behaviors to the villains: active, aggressive, independent, daring, powerful, and fiery. While patriarchy is being questioned in some social spheres, women still exist in a subordination role toward men.

According to the National Survey on the Dynamics of Household Relationships [48], the highest frequency of violence against women is found within an intimate couple relationship, making the husband, partner, or boyfriend the main aggressor.

Forty-nine-point-three percent of women in Mexico who have or have had a couple, whether by marriage, cohabitation, or courtship, have been assaulted by their partner at some point of the relationship.

The fact that violence is exercised in the household environment at the levels and frequency reported by ENDIREH's (2016) survey is indicative that gender equality is far from being a reality in the lives of the participant women in this study.

Limitations of This Study

The findings and conclusions of this study are limited to its population's characteristics: young adults with suicide attempted within the metropolitan area of Guadalajara, Jalisco, Mexico. It is crucial to reproduce this kind of study in other populations and age groups to comprise a greater knowledge on the problems involved in this study.

Abstract

This chapter identifies a range of protective and preventative strategies that can be utilized to diminish the prevalence of suicide. These include improved mental health access and treatment, the active development and facilitation of social and emotional support mechanisms, and the promotion of positive health-related behavior. There should also be increased research and policy attention to prevention and protection against suicide-related ideation and action.

Keywords

Suicide · Protective factors · Prevention

This chapter will attempt to review the literature in order to identify the factors that mitigate against suicidal actions and act as protection thereof. It will therefore provide a framework for prevention rather than intervention. Prevention can be achieved either by reducing or eliminating risk factors or strengthening protective factors. My focus will be on the literature that addresses the latter.

77

Suicide-related and self-harm behavior is either the result of hopelessness as part of a mental or physical illness spectrum, an impulsive or persisting response to acute or chronic distress, and/or existential despair and suffering. The occurrence of suicide also tends to distress the rest of society and hence it is treated as a psychiatric and medical emergency.

Decision-Making and Behaviour

There are several influences on behavior and decision-making. These influences culminate particularly in the interaction between emotion and cognition and the perceptions that inform healthy goal-consistent decision-making and behavior [6]. There is a debate regarding the extent to which the process of decision-making is affected by conscious and unconscious mental processes as well as the impact of context and the awareness of these various influences [19, 30]. It is therefore a complex interaction of genetics, developmental experience, environmental exposures, and stimuli and physiology. These all coincide with personality, and the literature on decision-making in suicide suggests that trait impulsivity is broadly correlated with the decision-making pathways that lead to suicidal actions [13]. This view interprets suicide-related actions as a response to perceived intolerable stress with a flawed estimation of the likely benefits of the outcomes [14]. These may also be affected by one's overarching worldview and the expectations that an individual has come to have on their life. Existentialist notions as described by Albert Camus posits suicide as the ultimate philosophical problem and frames it as one that must be resolved if one is to respond to the inevitable struggles and perhaps ultimate futility of life [34]. In so doing, suicide can be partially removed from the sphere of mental illness and be seen in the context of the decision-making that informs the human capacity to continue with life in spite of its challenges.

Resilience

While most epidemiological studies focus on the establishment of risk factors for disease and mortality, there is increasing attention being paid to protective factors. Developing protection seems especially important in the context of chronic conditions like depressive disorder [4]. Rutter [35] defined protective factors as those factors which modify, ameliorate, or alter a person's response to some environmental hazard that predisposes to a maladaptive outcome. This is intimately related to the concept of resilience which refers to an individual's capacity to adapt successfully to adversity. Resilience is increasingly being seen as a major protective factor against suicide [39]. The association of mental illness and psychological distress to life events and biological or social adversity suggests that it is in response to adversity that resilience and these protective factors become important [20]. In addition, protection against the development of pathological behavior must not only be seen as the absence of risk factors. There are also positive influences that enable an

individual to adapt positively to the demands of life, and these may be fundamental to the acquisition and maintenance of good mental health. These also in turn ensure that the exposure to risk factors will not result in the development of maladaptive responses. It also posits that resilience is a function of person-environment reciprocal interactions at the micro and macro levels, from caregiving to the environment in which one develops and lives over time in conversation with the evolving personality traits that lead to adaptation [41]. This in turn suggests that risk, protection, and resilience may be both time and context dependent and reflect an allostatic response to experience that is constantly changing based on anticipation and adaptation [21]. There will be individuals who are able to engage in life in a way that protects them from negative mental health and behavioral outcomes. Resilience is therefore a dynamic concept that is evolving alongside the individual's development [36]. Principal among the psychological factors that may affect this capacity for resilience are the traits of impulse control and emotional regulation [28, 29]. Enduring mental health has also been studied as although most individuals will develop a diagnosable mental disorder at some point in their lives, there is a minority that do not develop mental health problems. This phenotype is characterized by greater educational and occupational attainment, more adaptive personality traits, greater life satisfaction and higher-quality interpersonal relationships, and therefore greater resilience [38].

Mental Health

This brings us to suicidal behavior and its relationship to mental health. People with mental health problems are at increased risk for suicide, and two distinct pathways have been reported for this: one where life events and stressors preceded diagnosis and the other where diagnosis came before exposure to life stressors and events [9]. The combination of mental illness and life events and stressors seems to be necessary to result in suicide. However, mental health is not always implicated as some who die by suicide, do not have a mental illness, or may not have sought any help [8]. Still the risk of suicide associated with mental illness cannot be ignored and has been estimated to be as much as eight times that of those without mental illness; therefore, prevention and treatment of mental health problems is perhaps the first line of protection [37]. Adequate provision and access to mental health services must therefore be a priority in terms of prevention. This investment in mental health services is the first line of protection against the risk of suicide and suicidal behavior [33]. This will likely impact on the socioeconomic environment in a country and have both direct and indirect benefits on all aspects of health and well-being in a society [27]. One specific area of protection and prevention in this context is related to substance abuse [2] which alongside depressive and mood disorders, personality disorders, and psychoses constitute the greatest contribution to suicide. It has been reported that up to 40% of individuals seeking help for substance dependence have a history of suicide attempts. This is especially applicable to those with comorbid mental disorders and a range of psychosocial stressors such as relationship and financial stressors and a history of sexual abuse [46]. The burden of suicide is seen

particularly in alcohol use disorders [11]. Substance use disorders and poverty in the United States were found in one study to predict first-time suicide ideation and attempts [40]. All efforts designed to prevent the development of substance use disorders can therefore be incorporated into the arsenal of protective measures against suicide. Increased family cohesion, having strong confiding relationships with friends, and more empowering community and social support can protect against suicide ideation even when substance use may be present [17].

Social Factors

Protective factors can thus be summarized at this point to include the increased provision and access to care for mental health and substance use-related problems, facilitating increased family cohesion and strong interpersonal relationships with empowering social support. These factors are especially relevant to adolescents [1]. An interesting study among adolescents in Taiwan suggested self-esteem enhancement programs that are school based, improved emotion regulation skills, coping with stress strategies, early attention to substance use, and mental health issues alongside intensive anti-bullying measures were useful in reducing suicidal ideation [44]. Problem-focused coping strategies seem more effective than those that are emotion based and when applied with additional social support and self-esteem development can be useful in reducing suicidal ideation [31]. Higher levels of physical activity may also be associated with reduced suicidal ideation and attempts, but the evidence is not well researched at this stage [43].

In young people, dysfunctional mental processes can be modified to help prevent suicidal outcomes in high-risk vulnerable individuals. One of these is an intervention addressing maladaptive mood repair which seeks to modulate the ways in which sadness is regulated [22]. This approach seems to override the effect of both protective and risk factors. Teaching problem-solving skills and self-efficacy in working through the demands of life may also mediate against suicidality particularly when associated with impulsivity [16].

In the elderly, positive adaptation to the increasing loss of control over one's life and actions is thought to protect against suicide in the demographic group. Successful aging involves embracing the developmental changes that contribute to the loss of function by anticipating and engaging in positive lifestyle habits [15]. The effective management of chronic physical illness, early recognition and treatment of depression, and monitoring for abuse of prescription medication should be goals of engagement with the elderly when they engage the health services [10]. Helping older adults in articulating reasons for living and finding meaning in life may also act as protective factors in this age group [18]. Other important psychological factors include an internal locus of control, high levels of self-efficacy, and a general satisfaction with life [24]. Grit and gratitude may also be important with regard to persevering through difficulty which is likely to be more intimidating in older adults as well as being grateful for the life that has been lived. Rumination and brooding

also interact with grit and gratitude in a way where the latter diminishes the facilitating effect of the former [45].

Belief systems may also play a role in protecting against suicide. Moral objections to suicide (MOS) have been shown to be associated with diminished suicidal ideation and attempts in bipolar patients [12]. A review [42] found that MOS did counteract suicide and suicidality. There may be differential effects in some ethnic groups, so it is an area that requires further research [32]. It may also be a proxy for other factors as social and family networking and support.

Reasons for Living

Since suicidality is often a response to hopelessness, individuals who can identify definite reasons for living are more likely to be protected from suicidal-type actions even when they may be depressed or are facing adversity. Developing an optimistic perceptual framework within which to view life is therefore another protective factor against suicide [25]. The reasons for living may also coalesce with better coping skills and social support to improve resilience and in so doing protect against suicidal thoughts and behavior [3]. However, some have reported that diminishing reasons for dying is more effective than enhancing reasons for living in those already at risk of suicide [5]. Social connectedness as a means of reinforcing a sense of belonging is another useful construct in this regard. Its antithesis, thwarted belongingness has been found to be associated with suicidal ideation and may be mediated by clinical issues such as insomnia [7]. These may all act as contributors to the establishment of meaning in life which has been shown to be a buffer against suicidal acts in clinical and nonclinical populations [26].

Summary

In summary, therefore, early detection and treatment of mental health problems including substance use disorders; increased self-care, self-esteem, and self-efficacy; and social support and connectedness have all been identified as protective factors against suicide. Managing impulsivity, establishing reasons for living, and having a more optimistic view of the future are psychological states that also protect against suicide. Restricting the means of access to the means of suicide has also been a long-standing preventive and protective strategy for populations, but it will only be successful for individuals if the underlying mental health and psychosocial issues are also addressed. Cultural factors such as those mediated by religion and belief systems are also influential. General health-protective activity, for example, physical exercise and appropriate nutrition, serves to enhance well-being and acts as an indirect measure of prevention and protection against suicide. These may be seen as universal preventive and protective strategies [23]. The needs of specific groups, e.g., adolescents, the elderly, those with diagnosed mental health problems, the homeless, the incarcerated, and those with previous self-harm or suicide attempts,

may demand a wide range of strategies to ensure protection from suicide. One area of research that needs to be emphasized is the development and nurturing of resilience [39]. Resilience is useful at the universal, selected, and individual levels. The engagement with social and political policy makers to facilitate the development of these protective factors described will be critical to the success of the goal to eventually reduce suicide-related behavior. There is also a need for a greater research focus on protective factors as these will have a universal benefit and likely improve the mental health of populations.

Abstract

Although suicide is a major public health issue worldwide, mental health professionals and lay-people struggle to cope with suicide. Part of the problem comes from the myths, obsolete paradigms, and stigma associated with suicide, which results in anxiety and fear. However, most suicidal individuals want to live even when facing serious suicidal stress. Clinicians are, therefore, called upon to unlock the suicidal mind, relieve the suffering, and pay attention to the unmet needs of these individuals. There are so many unmet needs in individuals at risk of suicide. Too often, the medical model is imposed as a treatment plan. Therapists are more likely to treat the psychiatric disorder and, therefore, assume that this treatment also reduces suicide risk. In this way, the “one fits for all” model precludes understanding the suicidal mind, with its unique characteristics for each subject. Furthermore, there are still no agreed-upon models for managing patients accessing the emergency room and, besides, there is still no data on patient adherence to prevention programs at follow-up. One of the central elements of caring for people at risk of suicide lies in formulating the question, “What is it like to be suicidal?” To answer this question, the therapist must necessarily leave his

formal position and try to identify himself with the subject in crisis. It is an exercise that is not necessarily easy but for which you can train. Throughout this chapter, the reader is helped to understand the suicidal mind to facilitate this action. This chapter focuses on some of the unmet needs of suicidal patients and points to some key elements for clinicians in managing suicidal individuals. The concept of mental pain as the main ingredient of suicide is used to explore some of the most prominent features of the suicidal mind.

Keywords

Suicide

Although suicide is a major public health issue worldwide, both mental health professionals and lay-people struggle to cope with it. Part of the problem comes from the myths, obsolete paradigms, and stigma associated with suicide, resulting in anxiety and fear. However, most suicidal individuals want to live even when facing serious suicidal stress. Clinicians are, therefore, called upon to unlock the suicidal mind, relieve the suffering, and pay attention to the unmet needs of these individuals.

There are so many unmet needs in individuals at risk of suicide. Too often, the medical model is imposed as a treatment plan. Therapists are more likely to treat the psychiatric disorder and, therefore, assume that this treatment also reduces suicide risk. In this way, the “one fits for all” model precludes understanding the suicidal mind, with its unique characteristics for each subject.

Furthermore, there are still no -upon models for managing patients accessing the emergency room and, in addition, there is still no data on patient adherence to prevention programs at follow-up. The emergency department is often crowded where the clinician engages in data collection and brief assessments suitable for understanding the current crisis. The clinician’s need to collect preliminary information in a limited time often results in the patient’s image of a therapist who is not empathic and available. The result is that the patients will not be motivated to return and will not have observed the clinician’s skills for dealing with suicide risk.

One of the central elements of caring for people at risk of suicide lies in the ability to formulate the question, “What is it like to be suicidal?” To answer this question, the therapist must leave his formal position and try to identify himself with the subject in crisis. It is an exercise that is not necessarily easy but for which you can train. Throughout this chapter, the reader is helped to understand the suicidal mind to facilitate this action.

The increasing number of articles on suicide facilitates a significant increase in our understanding of suicide, but the therapist’s role as a critical element in determining the outcome of therapy with a patient at risk of suicide has received only limited attention.

It is widely believed that patients at risk of suicide arouse anxiety in the therapist, and their treatment takes on the aspects of a therapeutic challenge in which therapists confront the ghosts of death with their professional skills. In certain treatment

moments, it is evident how much the patient's life is subordinated to the therapist protecting his career. Experiencing the loss of a patient from suicide affects the personal and professional balance of the therapist significantly [1]. Furthermore, even the fear that this event may occur has consequences for the patient and the therapist. Some psychiatrists fear that a patient may choose suicide sooner or later in clinical practice. It is estimated that about half of all psychiatrists lose at least one patient from suicide during their career [2].

The emotional difficulties experienced after a suicide are greater than those experienced after other forms of death. The former is usually experienced as an offense to the therapist's ability to understand and help clients. He experiences the unpredictable, unknowable, and uncontrollable. The therapist's experience is, without doubt, of primary importance in managing the patient at risk of suicide.

However, both young therapists and those with more experience react similarly to the risk of a patient's suicide, showing anxiety reactions and feelings of incapacity [3]. Also, those who have thought of suicide are undoubtedly more vulnerable in managing the risk of suicide, especially if the therapist shows behaviors such as avoidance in the face of strong feelings, defensiveness, and passivity. In reading articles on the treatment of suicide risk, the frequency in which the word *assessment* or *evaluation* is used as a synonym for therapy is noteworthy. These articles are usually designed for guiding and helping the therapist treat the potentially suicidal person [4]. They contain a series of practical recommendations such as: "Do everything to eliminate firearms and drugs that are potentially lethal from the home of the suicidal patient"; "Check carefully the prescriptions of potentially lethal drugs"; "Alert family members"; and so on.

Such precautions or warnings may seem reasonable, but in reality, reflect a state of mind and a way of relating to patient suicides which often jeopardize successful treatment. As many suicidal patients are struggling with management and control of themselves, an excessive emphasis on precautions and on the evaluation, dictated by the therapist's apprehension, can facilitate one of the most lethal aspects of the suicidal person, that is, his tendency to make someone else responsible for keeping him alive. Some patients have an approach to therapy in which they attempt manipulation.

There is evidence in the literature in which therapy for the suicidal patient is based on the belief that the unbearable mental pain will eventually pass and that the crisis is time-limited. This belief is based on the example of other patients who found themselves in similar situations but who improved. It is often stressed that the behavior of the suicidal patient can interfere with therapy. Since treatment cannot help the patient if he is dead, it is necessary to remind the patient of his feelings for the spouse, children, or pets. To encourage a suicidal patient to live for the sake of his family reinforces what many patients already feel, that is, they are living just for the sake of others.

A therapist threatened by the fact that a patient may kill himself while he is in his care cannot help that patient. Indeed, the emergency measures necessary to prevent suicide and make therapy possible often reflect the therapist's anxiety and make treatment impossible.

Fear of responsibility when taking care of patients at risk of suicide, and the anxieties that this entails, serves as conscious motivation for therapists to avoid treating suicidal patients. Patients with suicidal tendencies are usually sensitive to the therapist's anxieties. Many suicidal patients (including those who eventually kill themselves) have learned to use the anxiety they can arouse in others by the threat of their death in a coercive or manipulative manner. Suppose the therapist, in the face of death threats, responds to the unreasonable demands of the patient. In that case, there will be an escalation of requests from the patient accompanied by growing anger and dissatisfaction in both the patient and the therapist. Unless these attitudes and patient expectations are explored, the therapist may make himself the slave of the patient, with terrible therapeutic results.

Wheat [5] conducted a retrospective study of the therapeutic interaction of 30 patients who had died by suicide during or after admission. He reported three factors that partially explain these suicides: (1) the refusal of the therapist to tolerate the patient's childlike dependence [6], (2) a discouraged attitude on the part of the therapist regarding treatment progress, and (3) an event or crisis of enormous importance for the patient that the therapist does not adequately recognize.

Bloom [7], in a similar study on the treatment of suicidal patients conducted by training psychiatrists, recognized that some elements appeared to be precipitating factors. Specifically, the rejection of specific behaviors of the patient by the therapist with verbal and facial expressions of anger, premature abandonment of the patient, reduction in the frequency of psychotherapy sessions, and a lack of availability of the therapist himself.

Lesse [8] emphasized that the experience and competence of the therapist, as well as self-knowledge, are of vital importance in the treatment of suicidal patients. He stressed the need for constant and competent supervision of the beginning therapists in training as they deal with patients with suicidal tendencies. In these cases, the dominant idea felt by the therapist is that a suicide attempt is a form of rejection of the therapist. At a professional level, it is necessary to correctly evaluate the patient's ability to act impulsively and follow his feelings of the moment. If the patient dies by suicide, the therapist might believe that he is not a good doctor. He may fear the disapproval of his colleagues, blame from the coroner, and bad publicity.

The Formulation of Suicide Risk

The so-called suicide risk formulation offers the clinician a valid method to assess the danger of suicide, which integrates the clinical presentation material, the history of the patient, his current illness, and the current mental state. There are five components in the formulation of suicide risk [9]:

1. Evaluate the patient's responses to stress suffered in the past, especially resulting from losses
2. Assess the patient's vulnerability to adverse life events, loneliness, contempt of self, and homicidal anger

3. Assess the nature of the resources available and external support
4. Evaluate the emergence and the emotional importance of fantasies of death
5. Evaluate the patient's capacity for analyzing reality.

Understanding the Suicidal Mind

Campaigns have been launched to make sense of what makes a specific individual suicidal. However, encountering a suicidal individual remains a challenging task for most professionals and common people. We know that suicidal individuals give definite warning signs, mostly derived from their ambivalence about ending their own lives. Among the constructs used to describe the wish to die, a simple but extraordinary model has proved, at least for its straightforwardness, to be useful in describing the suicidal mind. Edwin Shneidman [10] first posited that the suicidal individual experiences unbearable psychological pain (*psychache*) or suffering and that suicide might be, at least in part, an attempt to escape from this suffering. Shneidman [10] considered *psychache* to be the main ingredient of suicide. According to this model, suicide is an escape from intolerable suffering, emphasizing that suicide is not a movement toward death but rather an escape from intolerable emotion and unendurable or unacceptable anguish. Experiencing negative emotions, with an internal dialogue making the flow of consciousness painful and leading the individual to the ultimate conclusion, may be related to the fact that, if tormented individuals could somehow stop consciousness and still live, they would opt for that solution. Suicide occurs when the *psychache* is deemed by that individual to be unbearable [11].

For Shneidman [12], suicide is the result of an explosive mixture consisting of four basic ingredients. He listed such ingredients as follows: heightened inimicality (acting against the individual's best interest), exacerbation of perturbation (refers to how disturbed the individual is), increased constriction of intellectual focus, tunneling or narrowing of the mind's content (dichotomous thinking), and the idea of cessation: the insight that it is possible to stop consciousness and put an end to suffering.

The concept of inimicality, in this instance, refers to those attitudes of the individual that lead him to act in a way that is not at all friendly to himself, to the point of becoming his perverse enemy. In suicidal individuals, this state is present, and the individual is struggling with pressures of various kinds such as physical health, refusals, feelings of failure, pain, and other negative emotions. Unfortunately, the individual fails to manage these issues with the resources he has available.

Shneidman believed that in suicide, "death" is not the keyword. The keyword is "psychological pain" and, if the pain were relieved, then the individual would be willing to continue to live.

Two main concepts are relevant to this discussion: perturbation and lethality. Perturbation refers to how upset (disturbed, agitated, discomposed) the individual is, while lethality refers to the likelihood of an individual dying by suicide in the future.

Understanding the suicidal mind requires knowledge of the perturbed state of the individual in crisis since this provides the motivation for the individual to contemplate suicide. Therefore, asking where the suffering comes from and how it has changed and become more acute is a method of intervention that, although simple and intuitive, is often forgotten by those who are responsible for managing the person in crisis. In the internal debate, essentially involving ambivalence, being able to tune into the suffering of the person makes it possible to stem such ruminations and bring the discussion back to a position of vitality and hope.

Perturbation supplies the motivation for suicide; lethality is the fatal trigger. Everyone who dies by suicide feels driven to it and thinks that suicide is the only option left [13]. The concept of “constriction” is defined as tunnel vision or finding oneself with fewer options to cope with the suffering. Suicidal individuals experience dichotomous thinking, wishing either some specific (almost magical) total solution for their perturbation or for cessation, in other words, suicide. It seems that although there may be effective supports from family and friends, the individual is unable to benefit from them. The pleasant memories and their history in relation to others are not helpful, and the individual focuses on intolerable emotions and how to escape from them.

The concept of cessation comes into play when the individual develops the idea that one can put an end to the drama that takes place in his mind through dying. The individual then realizes that with death, he will bring a solution to his experience by eliminating all the elements that torment him in life.

Suicide results from an interior dialogue during which the mind scans its options [13]. During the early phases of this process, suicide is considered as an option, but it may be rejected a number of times. Shneidman [14] reported an emblematic process referring to the word “therefore” *“almost every decision that a person makes (based on some unspoken reasoning in the mind): it is the logical bridge between almost every thought and every action (or deliberated inaction). Among all the . . . therefore, I . . .” sequences that are possible in the mind, one of the most important ones is contained in the words: I’ . . . therefore, I must kill myself.”*

Suicide planning is often a long and complex process. The person begins to think of a propitious moment; he must have time to prepare. During the weeks and days preceding the actual planning until the act is implemented, the individual continues to dialogue with himself or herself with many thoughts. They can refer to the fact of not being worth anything for themselves, let alone for others, of not having been a success, of being a burden for oneself and one’s loved ones, that no one will ever love them, or to be a coward so much that one cannot even die by suicide. After debating, to overcome the survival instinct, the person must have, at least just before the act, such impulsiveness and aggression as to make a gesture against nature. Thus begins an increasingly tight challenge in which a moment of excitement in the mood may also occur during which the person sees salvation in suicide, begins to glorify the act, and configures it as a plan to put into practice, avoiding any interference on the part of the others. One must think of an act that appears to the subject as something forbidden but which feels necessary to improve his state. Suicide is an act that, in many cases, is premeditated for a longer time than is believed. Only after

this time does the act become an impulsive gesture. The individual has repeatedly thought about taking his own life, but this option, every time it occurred, although it was discarded, took on a greater value. At this juncture, the subject at risk of suicide begins to give signals in which he conveys the message of being tired of living, thinking about death, and wanting to die. It is a problem of human life for which “emotional storms” occur, great movements of ambivalence, and at the same time, changes in sleep habits, appetite, personal hygiene, and social relations. In this period of premeditation of the lethal act, the subject at risk also thinks of his loved ones, feeling regret and guilt for considering such a tragic solution. In some cases, there are also complex dynamics within the family, with the partner, or with friends, such that the suicidal individual almost reproaches them for not receiving adequate help.

Moreover, the subject at risk feels hopeless, and his mental pain feels unique, and he reaches this conclusion after experiencing the fact of not being able to communicate his suffering to the people assigned to help. The desire to die happens in each person with substantially unique motivations and thoughts, which makes him different from all other people at risk of suicide.

Shneidman [10] also considers that the main sources of psychological pain are shame, guilt, anger, loneliness, and despair originating in the frustrated and denied psychological needs. In the suicidal individual, it is the frustration of these needs and the pain that results from it, which he considers to be an unacceptable condition for which suicide is seen as the most appropriate remedy. There are psychological needs with which the individual lives and which define his personality and psychological needs which, when frustrated, induce the individual to choose to die. We could say that this is the frustration of vital needs. These psychological needs include the need to achieve some goals such as joining a friend or a group of people, gaining autonomy, opposing something, imposing on someone, and the need to be accepted and understood and receive comfort.

It is essential to monitor suicide risk at all times by considering warning signs for suicide, such as any change in habits, especially if insomnia is presented, and any reference to the wish to die. People may feel trapped and engage in maladaptive behavior, such as drinking alcohol and using psychoactive substances. Suicidal individuals also often put their affairs in order and give away symbolic items, as if they wish another person will take care of a prized possession, regardless of their economic value.

Studying the content analysis of the pain narratives of suicidal patients, Orbach [15] refers to specific features of the suicidal mind: These include a change in the self, experiences of self-estrangement accompanied by dissociative characteristics, a sense of worthlessness, emotional impoverishment, and loss of self-esteem. Furthermore, the mind is often characterized by the experience of loss, such as events that lead to an interruption in one’s sense of self-continuity and loss in one’s meaning of life. There are also oxymoronic experiences, extreme contradictions in feelings, thoughts, and desires – to live and die at the same time or grandiosity vs. humiliation. Besides, the language of pain points to the fact that ordinary words do not suffice to describe these idiosyncratic experiences.

Critical Appraisal of Psychiatric Disorders in the Context of the Suicidal Scenario

Unlike the decision to confine suicide risk to the symptomatology of psychiatric disorders, nowadays new insights into the phenomenon of suicide have led to considering that psychiatric disorders do play a contributing role. Still, a more profound understanding of the suicidal mind is needed [16]. Rather than categorizing the suicidal individual under the diagnosis of psychiatric entities, clinicians need to be able to recognize the drama occurring in the mind of a unique individual who may also be depressed, bipolar, or suffering from other disorders. Most psychiatric patients do not die by suicide. Psychiatric patients are suicidal only when negative emotions are so painful that suicide is the only option left and when the suicidal mind is hosted in an individual's mentally disturbed brain. Suicide is not, therefore, a specific and narrow symptom of depression. Instead, it is a behavior "combining features of a declaration of war with a petition for bankruptcy" [17] as well as having profound social implications [18].

Considering suicide risk to be fully a symptom impairs the opportunity to investigate and understand suicide. Attempts to explain, predict, and control suicide require understanding what suicidal thoughts and feelings mean to those who live it. Other than collecting a huge amount of data for research activities, efforts should also be directed to understanding first-person data of the subjective, lived experience. Such an approach is an essential complement to the objective, third-person data, and traditional science methods. Understanding the unbearable mental pain means thinking phenomenologically. Therefore, the development of suicidal tendencies can be traced back to a state with similar characteristics as falling in love but flipped for affective valences. It is a pervasive condition with both psychological and bodily roots that incorporate the individual as a whole. An unpleasant sensation is often localized in the chest and hypochondrium. The mind tries each option to release the tension but never finds a safe haven and ends up convinced that nothing will bring relief.

Clinicians should distinguish suicidal contents from a psychiatric diagnosis; it is, therefore, necessary to think that the elements that support the desire to dying constitute a process in its own right, with a logic typical of the mind that suffers and that tries to devise a solution to reduce and resolve this suffering. Since the nature of suffering that results in suicide is due to the personality of the individual, to his frustrated psychological needs, and to the wounds of the ego (defeats, humiliation, shame, etc.), one can, therefore, differentiate that suffering from the typical suffering of depressive symptoms. Subjects at risk of suicide develop a dichotomous thinking process because they reason with only two options when confronting the suffering that has become unbearable: continue to suffer or obtaining immediate relief from pain by suicide [13].

This process derives from an inner dialogue that the individual has with himself to seek a solution to his drama in mind. Independent of psychiatric disorder, clinicians are required to understand this complexity, without which the risk of suicide cannot be decoded. Suppose this process is not interrupted by a change through, for

example, help from someone. In that case, the individual approaches the final decision and, to quote Shneidman, *“The spark that ignites this potentially explosive mixture is the idea that one can put a stop to the pain. The idea of cessation provides the solution for the desperate person”* [12].

Communication of Suicidal Intentions

Among the myths often cited to describe idiosyncrasies in the phenomenon of suicidal behavior, classical suicidology, and current opinion state that people who talk about killing themselves rarely die by suicide, whereas most people who die by suicide have given some verbal clue or warning of their intentions. Some studies show that as many as two-thirds of suicide deaths share their intentions before dying by suicide. The study by Robins and colleagues [19] was probably the first attempt to address this issue through collecting data for a sample of suicides. The study remains one of the few contributions to the literature in this area. Despite the understanding of the communication of suicidal intent, no previous work has examined this fact through a meta-analytic investigation. A recent meta-analysis has shown how suicidal communications are key elements preceding suicides, confirming for this element for the first time [20].

Unlocking the Suicidal Mind by a Proper Understanding of the Subjective Experience

Unlocking the suicidal mind is the most challenging of all tasks. Many models describing suicide fail to provide a proper understanding of this multifaceted human condition. Stigmatization and fear often provide reasons for empathic disconnection. Furthermore, even when dedicated clinicians are willing to consider all of the patient's needs, we cannot imagine how much these patients suffer. In fact, in order for empathy to occur, it is necessary that we should have, in our own experience and in our own minds, some points of reference that correspond to those of the patients' experience of states of intense suicidal arousal or excitement (Maltsberger, personal communication 1988) [21, 22].

I agree with Zoe Boden [23] in her view of the experience of suicidal individuals, *“Acknowledging the felt aspect of the experience is, I will argue, necessary for developing a fuller understanding. Recognizing that feelings do not exist solely within a person, but between people, intersubjectively, is also necessary to understand the experience of suicidality more deeply. However, because feelings are immediate and sensory, I will suggest that there are times when understanding is difficult, not because the experience or meaning is hard to discern, but because the visceral power of understanding can feel too much. Feeling overwhelmed is one of the ways that we respond at the edges of our understanding. In our suicide research, there were times when understanding, really understanding, was more problematic than I initially wanted to admit.”* The individual must be understood holistically and

met in his or her experience as it is, rather than broken down into risk factors and behaviors.

I also support what suicidologist David Jobes [24] recently stated. *“First, the goal of the clinician is to develop a mutual understanding of an individual’s suicidality with the respective patient. This goal differs from the medical model emphasis, which tends to emphasize immediate and overriding emphasis on clinical diagnosis. Second, clinicians must be cognizant of a suicidal person’s potential anguish and total loss of self-respect. Many patients are likely to withdraw and express vulnerability when discussing their own suicidal thoughts and behaviors. Third, the clinician should express a nonjudgmental and supportive attitude toward the patient. Empathy is significant in strengthening the therapeutic alliance, and the patient should be validated as the expert of their own experiences. Fourth, suicidal crises are not simply about the present but also often about the past. In the exploration of the crisis/crises, the clinician should encourage the patient to tell their story in a narrative fashion. Fifth, new models are necessary to conceptualize suicidal behavior so that the clinician and patient share an understanding of the patient’s suicidality. An objective of this guideline is to not view the patient just as someone with psychopathology, but as someone with logical reasons for being suicidal. Sixth, the ultimate goal in clinical work is to garner a therapeutic relationship with the patient, right from the initial assessment.”*

Conclusions

There are still many unmet needs for suicidal individuals, and too often, such needs are disregarded as unimportant or of secondary importance. Clinical experience and recent data point to the need for a broader understanding of the suicidal mind. Although many scholars emphasize the importance of risk factors for suicide, such factors are usually static and derived from studies of people not necessarily representative of suicidal individuals in the general population. Such cohorts are sometimes small and belonging to narrow subpopulations, which impair proper generalization.

Each individual is unique, with a unique presentation of suicidal wishes. However, most individuals can refer their suffering to specific unmet needs, allowing categorization according to the nature of what is lacking in their lives.

Modern psychiatry now witnesses that which is conveyed in a paragraph of the introduction of DSM-5 [25] that is *“Diagnosis of a mental disorder should have clinical utility”* but *“the diagnosis of a mental disorder is not equivalent to a need for treatment. Need for treatment is a complex clinical decision that takes into consideration symptom severity, symptom salience (e.g., the presence of suicidal ideation), the patient’s distress (mental pain)”* and *“Clinicians may thus encounter individuals whose symptoms do not meet full criteria for a mental disorder but who demonstrate a clear need for treatment or care. The fact that some individuals do not show all symptoms indicative of a diagnosis should not be used to justify limiting their access to appropriate care”* (p. 20).

Aside from being an unexpected phenomenon, suicidal behavior is characterized by many warning signs that often allow key clinical decisions to save individuals' lives in crisis. The challenge of suicide prevention is to painstakingly develop a culture both in clinical populations and the general population to take care of suicidal individuals starting from their basic frustrated psychological needs. The task is to adopt a phenomenological approach that directs the attention of helpers inside the human experience of mental pain. Although an empathic understanding of the pain of suicidal individuals is not sufficient, it is the start of a process that might prevent the individual's suicide.

likelihood of engaging in suicidal thoughts and behaviors. The question of why someone would choose to live when considering suicide can be described from a positive psychology perspective as a reflection on meaning and purpose, indicating a shift from studying the role of negative emotional states toward a focus on satisfaction with life and psychological well-being. In studies of reasons for living, core factors shown to be protective against suicide include beliefs about coping, a sense of belonging, social support, and religion or spirituality. This chapter argues for a holistic approach to suicide prevention and treatment, which focuses not only on the cause of distress but emphasizes personal strengths and ameliorative resources.

Suicide prevention · Strength-based · Meaning and purpose · Psychological Well-being · Reasons for Living

Introduction

Suicide is a pressing issue, having been among the top ten causes of death in the USA since 2008 [1]. According to the World Health Organization, suicide claims approximately 800,000 lives every year [1], making it essential to develop and implement robust approaches to suicide risk assessment and intervention. Historically, suicide research and prevention efforts have focused on identifying risk factors and attempting to address the hypothesized causes of suicidality, such as emotional pain, hopelessness and helplessness, entrapment, negative personality traits, emotion dysregulation, and interpersonal difficulties. However, relying primarily on a problem-focused approach is clearly insufficient, as evidenced by continuously increasing suicide rates [1]. An alternative yet complementary approach of fostering reasons for living may serve to enhance suicide prevention by not only addressing problems but building on strengths.

Reasons for living can be conceptualized simply as an individual's reasons for choosing to continue to live when faced with the thought of suicide. The concept, as it is defined here, was popularized by Marsha Linehan and colleagues in 1983 when they began compiling a list of reasons why individuals in both clinical and non-clinical settings choose to stay alive when considering suicide [2]. The theory behind the study of reasons for living was that as negative beliefs contribute to the development of suicidal thoughts and behaviors, so would adaptive beliefs decrease the likelihood of engaging in suicidal thoughts and behaviors [2]. The question of why someone would choose to live when they are considering suicide may be conceptualized from a positive psychology perspective as a reflection on meaning and purpose, indicating a shift toward satisfaction with life and psychological well-being. The Reasons for Living inventory (RFL) has been shown effective in the assessment of suicide risk and has been translated and adapted, making it a viable option for suicide risk assessment across different populations and communities.

A Brief History

Suicide research has historically focused on factors contributing to an individual's decision to engage in suicidal behaviors. Toward the end of the twentieth century, researchers began to reconsider this unidimensional approach to suicide. Shneidman [3] posited that suicidal individuals experience considerable ambivalence and engage in an internal debate around living or dying. Kovacs and Beck [4] tested this hypothesis and found evidence that many suicidal individuals wish to live even while wishing to die. Additionally, individuals whose wish to die was more significant than their wish to live had the highest levels of suicidal intent compared with those whose wish to live was much greater, and those whose desires to die or live were balanced [4]. Kovacs and Beck [4] recommended that, in addition to addressing the suicidal patient's wish to die, therapists could incorporate strategies that foster the will to live in ambivalent patients.

In 1983, Linehan and her colleagues [2], inspired by stories of how Holocaust survivors maintained their will to live, theorized that non-suicidal individuals have specific characteristics, such as "beliefs about life and expectations for the future," that could serve as *reasons for living*, or important reasons to stay alive and not commit suicide despite stressful life-events. On the other hand, suicidal individuals were believed to lack these "adaptive, life-maintaining characteristics." In their study, Linehan and colleagues identified six main categories of reasons for living (i.e., survival and coping, responsibility to family, child-related concerns, fear of suicide, fear of social disapproval, and moral objections) and found that suicidal individuals indeed had fewer reasons for living and ascribed less importance to them. These results supported the theory that non-suicidal individuals differ from suicidal individuals in the extent to which they endorse having important reasons for living. The RFL was developed using the identified categories to assess the extent to which an individual values various reasons for living. These reasons are viewed as protective factors against suicide, and many suicide assessments and treatments now incorporate reasons for living formally and informally rather than focusing solely on suicidal intent. The RFL (which has been validated, adapted for various populations, and translated into multiple languages) has been used to assess risk for suicide, while other suicide assessments may simply ask patients to list reasons for living and reasons for dying and rank the importance of these reasons. Likewise, clinicians may encourage suicidal patients to identify reasons for living to mitigate suicidality.

A Holistic Approach to Suicide Prevention

Traditionally, mental healthcare has been concerned with understanding the root of psychological distress in order to resolve the cause of the distress and ease the individual's psychological pain. Problem-focused interventions grounded in theory often adopt a problem-solving approach or incorporate cognitive restructuring. The problem-solving approach suggests that the individual's suffering stems from

lacking the necessary skills to solve problems effectively and therefore teaches problem-solving skills (e.g., clearly defining the issue, brainstorming alternate solutions, and evaluating the effectiveness of options) to address these deficiencies [5]. Conversely, cognitive restructuring attributes symptomology to maladaptive thoughts and encourages the patient to identify, test, and correct these distorted cognitions and beliefs [5]. Rather than taking a problem-focused approach, it is suggested that an equal, if not greater, emphasis is placed on enhancing protective factors than is traditionally placed on problem-solving approaches. At the beginning of the twenty-first century, Seligman and Csikszentmihalyi [6] critiqued psychology's focus on pathology and urged psychologists to shift their attention to reinforcing positive qualities, thus ushering in the field of positive psychology. Positive psychology focuses on positive experiences and character traits, and, in the context of suicide, it examines reasons for living, individual strengths, and other protective factors instead of risk and vulnerability factors [7]. Several alternate theories regarding suicide, such as the broaden-and-build theory, have emerged from positive psychology in recent years [7]. Additionally, the nascent field of "positive suicidology" has developed various strength-based approaches to suicide prevention, such as fostering resilience, meaning, purpose, quality of life, and psychological well-being [7].

While it remains of vital importance to address the cause of distress, a more holistic approach, which also focuses on the strengths and resources of the individual, is outlined here. The RFL is one of the ways to gain an understanding of the strengths of the individual, including their unique differences, cultural identity, and values.

Problem-Focused Approaches

Problem-solving and cognitive restructuring are common problem-focused approaches used to treat suicidal patients [5]. These approaches target concomitant factors of suicide, including a) *emotional pain*, b) *hopelessness*, c) *entrapment*, d) *interpersonal difficulties*, e) *emotion dysregulation*, and f) *personality traits* [5]. The following sections provide an overview of these issues and their relation to suicide. Problem-focused approaches to each factor will be described along with ways strength-based approaches and reasons for living can be used as well.

Emotional Pain

Emotional pain is an essential factor associated with suicide risk. Shneidman [8] coined the term "psychache" to refer to the psychological anguish a person feels. He proposed that this psychache, or emotional pain, results from an inability to meet the psychological needs an individual believes to be necessary for his or her life. Suicide occurs when the perceived psychache becomes unbearable. From this perspective, suicide is a solution to end this intolerable pain, and suicide prevention efforts aim to decrease the intensity of the subjective psychache by addressing the unmet needs specific to the individual. Common unmet needs associated with suicide include the

need for control, independence, belonging, and acceptance and the need to avoid humiliation and failure.

Clinicians can help suicidal patients generate alternative solutions and compare the effectiveness of these alternatives in meeting their needs with suicide. Additionally, cognitive restructuring can increase the suicidal patient's tolerance for distress and reduce psychache. An exploration of reasons for living could broaden the suicidal patient's perspective, so his or her attention is not solely focused on the unmet psychological need and thus reduce subjective pain.

Hopelessness

Although initially identified as a risk factor for depression, *hopelessness* has been found to be a strong predictor of suicide [9]. Hopelessness involves expectations of adverse outcomes (i.e., desired outcomes will not occur, but aversive outcomes will) and helplessness (i.e., one's actions do not affect outcomes) [9, 10]. This negative mindset usually results from attributing an adverse event to stable and global causes (i.e., causes that are long-lasting and affect many domains); believing the consequences of the event are important, immutable, and far-reaching; and attributing negative characteristics to oneself [10]. Hopelessness contributes to the belief that the situation will not improve and there is nothing one can do to resolve the problem, which can, in turn, lead to or exacerbate emotional pain, thus increasing the risk of suicide.

Treatments that focus on developing the patient's problem-solving skills can empower them and increase self-efficacy for resolving issues, thereby decreasing helplessness and hopelessness [11]. Cognitive restructuring targets negative outcome expectancy by challenging misconceptions about the world, the future, and self, as well as associated maladaptive thinking styles [9, 10]. Suicide prevention efforts should also promote hopefulness in the patient. Reasons for living has been shown to be negatively correlated with hopelessness [11], potentially because it can instill a renewed sense of hope. Focusing on the suicidal patient's strengths could simultaneously dispel hopelessness and restore hopefulness as well.

Entrapment

Suicide as a method to escape has been observed frequently in clinical cases, suggesting that *entrapment*, or perceived inability to escape, is an important contributing factor [8, 12]. In fact, entrapment is a critical component of the escape theory of suicide and is associated with emotional pain and hopelessness. Baumeister [12] first proposed that entrapment occurs when outcomes or circumstances fall short of expectations (e.g., when an intimate relationship ends or when one becomes unemployed). According to his escape theory, the disappointing situation triggers self-blame and negative views of self, which in turn leads to increased self-awareness of one's shortcomings and negative emotions. One will attempt – and fail – to escape this aversive state by disengaging from meaningful thought and higher-level thinking and entering a state of cognitive deconstruction. Cognitive deconstruction is comprised of a constricted focus on the present and closed-mindedness. In this state, the unpleasant present seems interminable, and a

different future is hard to imagine; behaviors are motivated by immediate goals rather than more distal ones; and thoughts are overly concrete and rigid, without any abstraction or higher mental awareness. Consequences of cognitive deconstruction, including decreased inhibitions and irrational thinking, increase the risk of suicidal behaviors as a way the escape from reality and the feeling of entrapment.

Entrapment is also a concomitant factor with emotional pain and hopelessness. Schneidman [8] theorized that suicide occurs when psychache, increased negative attitudes toward oneself, a narrowed perspective, and a strong desire to end the pain are present simultaneously. The suicidal person experiences tunnel vision, which limits their cognitive abilities to consider all available options or recall positive memories [8]. This is similar to the rigid characteristics of cognitive deconstruction, where impaired cognitive processing leads to dichotomous thinking and the need for either a perfect solution to the problem causing the pain or cessation of the pain [8]. Cognitive deconstruction can also lead to hopelessness as a result of the inability to imagine a more acceptable future and the lack of realistic long-term goals [12]. The hopeless individual may then feel trapped because of the belief that there is no solution to the problem and there is nothing, except commit suicide, to change the situation. Ultimately, entrapment is the result of “attentional fixation,” which posits that the suicidal patient has a narrowed perspective that prevents them from identifying alternatives to resolve their distress and a preoccupation with suicide as the sole way to resolve this psychological pain [11]. Thus, for the suicidal individual who feels trapped, suicide may be perceived to be the only way to escape from the circumstances.

As with emotional pain and hopelessness, problem-solving approaches can allay feelings of entrapment by showing the suicidal patient that other options do exist and can be more effective at resolving the issue. Cognitive restructuring addresses entrapment in the escape theory by establishing more realistic expectations, challenging negative views of self, and supporting higher-level thinking. Positive psychological approaches can also be effective in lessening the sense of entrapment. Identifying reasons for living reminds the suicidal patient of what they hold dear in life and can shift their focus, helping the patient recall life-sustaining memories and thoughts, broadening their thinking. In fact, the broaden-and-build theory suggests that positive emotions broaden an individual’s thinking and behaviors, so they are more likely to generate novel ideas and engage in a greater variety of actions [7]. According to this theory, evoking positive emotions may be sufficient to counter the constricted perspective and alleviate entrapment.

Interpersonal Difficulties

One critique of emotional pain and hopelessness as predictors of suicidality is that they are too general. While many people who attempt suicide feel emotional pain and hopelessness, most people who experience one or the other do not engage in suicidal thoughts or behaviors [13]. In his interpersonal-psychological theory, Joiner [13] suggests that emotional pain and hopelessness lead to suicidality when they are triggered by *interpersonal difficulties*, specifically perceived burdensomeness and thwarted belongingness. Perceived burdensomeness is the belief that one is

ineffective or incompetent and, thus, is a burden to others [13]. This perception contributes to emotional pain, especially if one believes that loved ones are negatively impacted, and can lead to entrapment and feeling hopeless. Suicidality emerges when one believes the perceived burdensomeness is permanent and one's death would be better for others. According to Joiner, a sense of belonging develops from interacting with others and feeling cared about [13]. Thwarted belongingness then is the consequence of a lack of positive interactions and a feeling of being uncared for: interactions may be unpleasant or infrequent, and the individual may not feel connected to anyone. Thwarted belongingness is not merely loneliness but the feeling of total alienation [13]. This social exclusion is painful and increases the risk of suicide.

Problem-solving can mitigate feelings of ineffectiveness and incompetence associated with perceived burdensomeness by identifying ways that the suicidal individual can contribute to their community and be of assistance to loved ones. This approach can also be used to increase a sense of belonging by developing strategies to improve social integration, targeting deficits in social skills, and decreasing interpersonal conflicts. Cognitive restructuring can challenge suicidal patients' negative beliefs about themselves and their place in the world. In addition to these problem-focused approaches, strength-based approaches and reasons for living can be particularly beneficial for addressing these interpersonal difficulties. Identifying individual strengths directly counters the belief that one is ineffective. Clinical observations have found that identifying even one close relationship can be sufficient to deter suicide [13]. Similarly, identifying reasons for living related to responsibility to family and child-related concerns can reduce feelings of thwarted belongingness enough to lessen suicidality.

Emotion Dysregulation

Another risk factor for suicidal behaviors is *emotional dysregulation*, which is the result of heightened emotional vulnerability and poor emotion regulation [14].

Emotional vulnerability is characterized by sensitivity to emotional stimuli, emotional intensity, and the length of time needed to return to baseline [14]. High emotional activation also biases perceptions (i.e., interpretations and judgments made are consistent with the mood state) and memory (i.e., mood-congruent events are more easily encoded and recalled). These cognitive biases increase emotional sensitivity, thereby facilitating reactivation and prolonging the affective state [14]. Emotion regulation usually involves experiencing and labeling emotions before reducing stimuli that activate negative emotions [14]. Individuals with poor emotion modulation skills are more likely to attempt to control their emotions by merely telling themselves not to feel in specific ways, painful emotions that cannot be suppressed are viewed as problems, and suicidal behaviors are believed to be the solution to the intolerable pain. Emotion dysregulation relates not only to emotional pain but also to entrapment and interpersonal difficulties. Emotionally vulnerable people may be susceptible to feeling intense emotional pain for extended periods of time due to their heightened emotional sensitivity. They may also try to escape from the pain through cognitive deconstruction. Additionally, the cognitive biases

associated with affective reactivity can contribute to interpersonal difficulties by making negative interactions more salient. Thus, it can be challenging to resolve relational conflicts, leading to unsatisfactory relationships, feelings of not being cared about, and thwarted belongingness. Poor emotion regulation makes it difficult to tolerate the negative emotions that arise during relationship conflicts as well. This impedes one's ability to apply interpersonal problem-solving skills to the situation, which can exacerbate relational strains and impede belongingness. Addressing emotion dysregulation primarily uses a problem-solving approach focused on developing skills in deficient areas. Emotion regulation and distress tolerance skills, mainly through mindfulness techniques, can be taught to improve emotion regulation, while interpersonal skills can reduce conflicts and prevent thwarted belongingness [14]. Cognitive restructuring can target the biases associated with emotional activation, potentially decreasing emotional vulnerability. Paying more attention to positive emotions can counteract the salience of negative emotions and the associated biases [14].

Personality Traits

The diathesis-stress model of suicide proposes that diatheses, or predispositions, interact with environmental stressors to produce suicidality [11]. Fewer stressors are needed to trigger suicidal intent in someone with more individual risk factors. Diatheses include personality traits, such as trait-like cognitive styles and perfectionism.

Maladaptive cognitive styles can be trait-like or relatively chronic and stable [11]. For example, one can hold a persistently negative view of oneself even in the absence of an adverse event to trigger such a response. These trait-like cognitive styles resemble one's general outlook on life [11]. Dysfunctional thought processes described previously (e.g., attributing adverse outcomes to internal, pervasive, and ongoing causes; fixating on negative events and circumstances) can reflect the negative schemas one holds regarding oneself, the world, and the future [11]. These cognitive styles contribute to the onset and maintenance of the other concomitant factors of suicide described in this section (i.e., emotional pain, hopelessness, entrapment, interpersonal difficulties, and emotion dysregulation). Having these maladaptive cognitive predispositions would substantially increase the risk for suicide. These dysfunctional attitudes can also be indicative of other negative personality traits like perfectionism.

Perfectionism, particularly socially prescribed perfectionism (i.e., the need to meet others' expectations), is positively associated with suicide [11]. Perfectionism often involves maladaptive cognitive processes, such as all-or-nothing thinking and a tendency to focus on imperfections and failures, increasing the risk for suicide [11]. Elevated stress due to the perceived need to meet various expectations can increase vulnerability to emotional pain and hopelessness when faced with setbacks. Perfectionists usually have unrealistic standards and expectations, which can also result in entrapment when confronted by failure and disillusionment with oneself.

Other personality traits, such as neuroticism, low self-esteem, impulsivity, introversion, and borderline characteristics, are also more prevalent in suicidal patients [11]. Many of these involve dysfunctional attitudes and maladaptive cognitive styles, while others are more closely linked with interpersonal difficulties (e.g., introversion) or emotion dysregulation (e.g., borderline characteristics). Although personality traits do not directly lead to suicide, it is evident that they are interrelated. Moreover, they interact with the environment and other suicidal risk factors.

Since personality traits are closely related to other suicide factors, similar treatment approaches can be used. Additionally, increasing self-efficacy for solving problems can challenge negative views of oneself and improve self-esteem. Maladaptive thought processes and perfectionism could abate with cognitive restructuring, and strength-based approaches focused on one's strengths and developing a positive outlook.

Strength-Based Approaches

While it is important to address what causes or exacerbates suicide risk, it is also essential to strengthen protective factors and reduce risk factors to promote positive outcomes in suicide prevention [15]. The ability to adapt to stressful and adverse events may be viewed as an outcome of several protective factors (e.g., healthy interpersonal and emotional relationships, strong self-esteem, problem-solving social skills, strengthened support networks, emotional bonds, and trust), enabling the person to respond positively, overcome, and enhance their emotional response [15].

Resilience

A focus on resilience is vital in suicide prevention as “Persistence and Resilience” have been identified as catalysts for other support factors when facing risk factors of suicide such as social, interpersonal, and emotional stressors [15]. Additionally, one protective factor an individual can hold includes resilience; resilience is fundamental in the “realization of purposes, altruistic actions, resignification of lived experiences, strengthening of self-esteem and self-acceptance, desire to live, search for dreams and goals, and the de intention to ‘move forward’” [15]. This research suggests the importance of resilience through permanence and strengthening of supporting resources to reduce the risk of suicide [15]. To increase protection against suicide and enhance specific resilience factors, clinicians can play a role in developing therapies by examining the interactions of resilience and other factors (e.g., Negative Life Events) [16].

A closer look at the older adult population illustrates the importance of understanding resilience's impact on suicide. With an increased capacity for spirituality and transcendence with age, older adults demonstrated more psychological resiliency compared to younger adults, confounding other research suggesting high rates of suicide among older adults and necessitating an enhanced understanding of models of suicide risk and resiliency [17].

Meaning and Purpose

Findings by Heisel and Flett are consistent with prior research suggesting those who reported more significant meaning in life (MIL) or purpose in life (PIL) reported significantly greater psychological well-being, less psychological despair, and less suicide ideation [17]. Heisel and Flett's work is the first research demonstrating that MIL appears to protect against the onset or exacerbation of late-life suicide ideation [17]. According to Frankl [18], those perceiving life to continue to hold meaning (i.e., MIL), irrespective of one's current conditions or circumstances, may be protected from the incipient despair that is often associated with crises, losses, transitions, and stressors that can accompany aging [17, 19]. Aspects that mitigate the negative impact of physical, emotional, interpersonal, and situational challenges work by fomenting meaningful opportunities and purposeful activities related to the perceptions of one's personal identity and interpersonal relationship, thus building recognition of meaning in life, which can protect against suicide risk [17]. In a study of Australians aged 61 to 95 years ($n = 104$) examining the sense of belonging and reasons for living in an older adult population, those who felt a greater sense of belonging and those who were motivated to belong reported more survival and coping beliefs; a higher sense of belonging was related to more reasons to live overall [19]. Participants with more child-related concerns, greater responsibility to family, and more survival and coping beliefs had a higher sense of belonging [19]. These findings suggest that increasing an elderly person's sense of belonging may increase survival and coping beliefs (a factor of Reasons for Living), which may reduce suicide in older adults. The significant link between a sense of belonging and coping beliefs shines a light on these beliefs' importance in suicide prevention [19].

Quality of Life

Quality of Life is multidimensional. Like reasons for living, quality of life is a mental state, and it aims to describe an individual's well-being by summarizing an individual's physical, mental, and social functioning [20]. It is essential to focus intervention and treatment efforts on improving Quality of Life (QoL), to take further steps in suicide prevention, especially in adolescents with emotional and peer-related problems, as suggested by Goodman and colleagues' with their Strengths and Difficulties Questionnaire [20]. Regular assessment of quality of life is important since low QoL within the month before death was found to be a significant predictor of completed suicide [20]. Still, it does not include screening for psychopathology – which has been correlated with lower QoL in children compared to healthy peers [20]. In both nonclinical and clinical studies [21, 22], lower QoL has been associated with suicide when compared to people without suicidal thoughts. This association is also consistent after logistic regression was done to assess the impact of sociodemographic (e.g., age, gender, ethnicity, living satisfaction, living situation, and family SES) and clinical factors (e.g., depression, bipolar, schizophrenia) [20]. It has been found that quality of life directly affects the desire to hasten death and is mediated by depressive symptoms, loss of meaning and purpose, loss of control, and low self-worth [23]. In a sample of palliative care patients, most patients overall reported good quality of

life, which was mediated by the low burden of depressive symptoms, low levels of demoralization, high levels of perceived control and self-worth, and low desire for hastened death [23]. A significant inverse relationship between quality of life and desire to hasten death is consistent with qualitative studies which found that the desire to hasten death is future-focused [23]. This relationship is believed to be related to the person's perceived control in their life, as determined by fear of distress and not coping, rather than their current levels of distress or coping ability [23].

Psychological Well-being

Psychological well-being is defined as a multidimensional model of understanding a person's experience of making meaning and finding fulfillment, which serves to counteract the experience of meaninglessness which is believed to lead to suicide [24]. The Psychological Wellbeing Scale (PWB-42), developed by Ryff in 1989 and adapted by Krok in 2009, is based on the eudemonic concept of happiness, measuring six aspects of well-being and happiness: self-acceptance, purpose in life, positive relations with others, personal growth, environmental mastery and autonomy, which may predict orientation toward suicide prevention [24]. Holistic approaches to psychological well-being can include preventative health and can be used to address clinical issues such as suicide [24].

Linehan and colleagues postulated a protective factor against suicide are Reasons for Living, which is defined as reasons for "staying alive" and "not killing [one]self," such as Family-related Positive Life Events [2]. Research has found that Family-related Positive Life Events (PLE) and Reasons for Living are both negatively associated with suicidal ideation (SI) [16]. It is believed that focusing on reasons for living serves to increase psychological well-being and buffering the effects of Negative Life Events on SI [16]. Huffman and colleagues found that PLE's role in SI reduction can enhance patient well-being through short positive psychology exercises, such as writing gratitude letters or "counting the blessings," which entails recalling and in detail recording three events over the past week where they felt grateful [16]. Low-level well-being (World Health Organization-5; WHO-5) has been correlated with a high level of suicidal intent, depression and hopelessness [25]. WHO-5 is a brief depression screening instrument which measures the subjective psychological experience of well-being. A low score on a psychological well-being measure, such as WHO-5, may serve as an indicator for a clinician to investigate further the severity of depression and hopelessness associated with suicidal behaviors [25].

Reasons for Living as a Strength-Based Approach

Stressful life events are often viewed as a precursor to suicidal behavior; however, most people experiencing stressful events do not attempt suicide [26]. It is believed that purpose in life and reasons for living serve as protective factors against suicidal behavior when individuals are faced with stressful life events. Although purpose in

life and reasons for living have some overlap, these factors have distinct differences. Purpose in life refers to the global belief in one's life purpose; in contrast, reasons for living are focal factors that prevent an individual from committing suicide [26]. Positive effects on reasons for living were found from avoidance-oriented coping, which includes temporary distraction from problems, suggesting the utility of short-term approaches by allowing individuals to reflect on what makes their life worth living [26]. It is postulated that temporarily shifting focus away from their problems allows individuals to see other important aspects that make life worth living [26]. Research by Wang and colleagues suggests suicide prevention should also focus on increasing reasons for living and purpose in life, in addition to already used approaches like increasing task-oriented coping and decreasing emotion-oriented coping, by instilling both positive cognitions and positive affect [26].

Reasons for Living are adaptive beliefs and expectancies that mitigate suicide risk [2] and are compatible with cognitive and cognitive-behavioral theoretical approaches to suicidal behavior. Reasons for Living may be a better means to address suicide compared to measures that are not patient-centered and attempt to measure constructs that are difficult to measure, such as Quality of Life, as there is no single agreed upon definition and are usually relative to individual or cultural expectations and goals [27]. The RFL was created by asking participants three questions. For context, participants were asked to list (1) their reasons for not killing themselves at the point in their lives when they had most seriously considered killing themselves; (2) reasons why they would not now kill themselves; and (3) the reasons they believed kept other people from killing themselves [2]. Participants generated 72 unique responses, which were then distilled using factor analysis to yield the 48-item questionnaire [2] that is now widely in use and the subject of this chapter.

Overview of the Subscales

In addition to the wealth of research findings that support the efficacy of total RFL scores in suicide prevention, the subscales, and items within these subscales have been repeatedly shown to be correlated with suicidal ideation and behaviors. The RFL [2] consists of six subscales: 1) Survival and Coping Beliefs, 2) Responsibility to family, 3) Child-Related Concerns, 4) Fear of Suicide, 5) Fear of Social Disapproval, and 6) Moral Objections to Suicide.

Survival and Coping Beliefs

The Survival and Coping Beliefs subscale combines a number of beliefs about life and living and includes positive expectations about the future (i.e., "I believe everything has a way of working out for the best"), beliefs about one's ability to cope with whatever life was to offer (e.g., "I believe I can learn to adjust or cope with my problems"), and beliefs about imbuing life and living with specific values

(e.g., life is all we have and is better than nothing”). In both of Linehan’s original samples, the Survival and Coping Beliefs scale was identified as one of the most useful in differentiating the groups [2]. In terms of cultural variation, two young adult studies, one performed in China and another in Canada, both demonstrated that Survival and Coping Beliefs have possible protective effects in suicide [28]. In another study, Survival and Coping Beliefs scores were strongly, positively correlated with social desirability and correlated significantly and negatively with both past suicidal ideation and future likelihood of suicide [26]. Survival and Coping Beliefs (SCB) were related to suicidal behaviors and are consistent across age groups. The relationship’s stability and strength suggest SCB may represent necessary and important beliefs in an individual’s ability to cope with life stresses [29].

Responsibility to Family

The Responsibility to Family subscale illustrates the impact suicide would have on the family, including how the family would feel and the needs of the family (e.g., “It would hurt my family too much, and I would not want them to suffer” or “My family depends upon me and needs me.”). Family connectedness has been shown to be significantly protective against suicidal ideation and attempts. Individuals who reported never having suicidal thoughts had greater Responsibility to Family scores than the Brief Suicide Ideation, History of Serious Ideation, and History of Parasuicide combined. Further, those who reported brief, nonserious suicidal ideation had greater Responsibility to Family scores when compared to both those who reported serious past ideation and past parasuicidal behaviors combined [29]. Responsibility to Family scores were negatively correlated with past ideation and future probability of suicide [29].

Child-Related Concerns

The Child-Related Concerns subscale assesses possible effects on their children (e.g., “It would not be fair to leave the children for others to take care of.”). Linehan’s original study found that child-related concerns differentiated between individuals who were currently suicidal and those who were non-suicidal in a sample of hospitalized individuals [2]. Also, among this group of hospitalized individuals, this subscale distinguished between individuals who were experiencing current suicidal ideation and those who have attempted suicide in the past. Finally, Linehan and colleagues [2] found that this subscale differentiated between individuals who had no reported history of suicidal behavior or brief ideation and those who had a reported history of serious ideation or behavior in a general population sample. Studies have found important differences in responses to this subscale in terms of culture, gender, and age, indicating that the utility of this subscale is particularly variable based on the identity, cultural context, and phase of life of the respondent. This will be discussed in more detail later.

Fear of Suicide

The Fear of Suicide subscale measures beliefs about the act of suicide, including the reality and feelings of fear about the act (e.g., “I am afraid of the actual ‘act’ of killing myself (the pain, blood, violence) or “I am afraid of death.”). This subscale reflects the fears and concerns that an individual may have about suicidal behaviors encouraging the individual to face the reality of pain and violence that may result from their attempt to escape their emotional pain. Studies have found differences in responses to this subscale based on an individual’s history of suicidal behaviors, differentiating between those who have attempted suicide and those who have not. Support for this subscale is limited – while those who have engaged in suicidal behaviors respond differently to this subscale than individuals who have not engaged in these behaviors, this subscale tends to be less powerful of a discriminating factor than other subscales ([30]).

Fear of Disapproval

The Fear of Disapproval subscale assesses the person’s beliefs about how others would think about them and the act of suicide (e.g., “I am concerned about what others would think of me” or “I would not want people to think I did not have control over my life.”). This subscale may be the most influenced by cultural identity as it often reflects the values of community-focused individuals who perceive a sense of shame or responsibility to others in their community. Interestingly, this subscale has been found to be one of the subscales most significantly negatively correlated with suicide attempts among depressed individuals [30]. The RFL translated in Mandarin found that the Fear of Social Disapproval is not related to prior suicidal attempts; it is still negatively correlated with current suicidal attempts, the frequency of suicidal ideation, history of suicidal threats, and future likelihood of suicide [28].

Moral Objections

The Moral Objections subscale addresses beliefs about the morals around suicide (e.g., “I consider it morally wrong” or “I believe only God has the right to end a life.”). The Moral Objections subscale of the RFL has repeatedly been linked to religious and spiritual beliefs [31]. Individuals who reported never having suicidal thoughts had greater Moral Objections scores than the other SBQ groups [29]. Older adults score higher on the religious subscale [32]. Responses related to this subscale can distinguish between individuals with more serious suicidal ideation from those with less serious ideation [33]. Individuals with religious affiliation obtained a higher total score on the RFL than those who were non-religious [28]. Among individuals who have attempted suicide, this subscale has been found to differentiate between high lethality (lower moral objections) and low-lethality (higher moral objections) attempters [30].

Adaptive Approach to Suicide Prevention

The RFL is not only an effective measure of suicide risk; it is an intervention that is adaptive to age, language, and cultural context.

Reasons for Living by Age

It makes intuitive sense that an individual's reasons for living would change with age, based on their life-stage and evolving values, priorities, and meaning-making. When comparing older adults to younger adults, for example, older adults score higher than younger adults on the RFL items that assess moral objections and child-related concerns [34]. Conversely, it is essential to identify common reasons for living across the lifespan as this can provide a general point of intervention or a common approach appropriate for individuals of different ages.

Older Adult

While the original RFL was not developed or validated among older adults, the original RFL has been found helpful in reducing suicide risk among older adults [34]. Moreover, researchers created an older-adult version of the RFL (RFL-OA) for which researchers distributed open-ended surveys to 500 older adults and identified 69 unique reasons for living with similar themes as the original RFL, but more reasons for living pertaining to family and friends, religious beliefs, and moral objections to suicide [32]. A particularly strong protective factor among older adults is a sense of belonging [19], which can be described as a perception of personal involvement in one's environment or social system [18]. One study using the RFL-OA found that overall coping was positively related to reasons for living, particularly the subscales of survival and coping beliefs and child-related concerns [7]. Older adults score significantly higher on the original reasons for living in the moral subscales and higher on religion items of the RFL-OA [32].

College Students

The College Student Reason for Living inventory (CSRLI) was developed with results also different from the original RFL. The development of the CSRLI found 46 reasons for living with similar factors from the original RFL, the only exception was the Child Related Concerns factor not included, and a unique factor representing College and Future Related Concerns emerged [35]. Those of higher self-perceived suicidal risk has consistently been found to have significantly lower reasons for living on the total CSRLI scale [35].

Young-Adult

The development of the Reasons for Living Young Adult (RFL-YA) had a similar approach to the RFL-A with the use of a pool made up of 42 college students in several psychology classes [36]. In addition to a pool of college students, the version of the RFL-YA took 12 items from the RFL-A and initially generated 54 more fully

investigated items by a team that included a psychologist and youth counselor, which helped conclude a 52-item scale for the RFL-YA [36]. RFL-YA in India - Coping beliefs, family relationships, and future expectations were correlated with suicidal ideation [37]. Individuals reporting higher scores on the RFL-YA subscales and total score were able to identify significantly more positive protective factors than those with lower scores [36]. In the RFL-YA, the study found that when looking toward the future, it showed that strength of religious faith was the strongest predictor among individuals with serious ideation and those who had a previous suicide attempt [33].

Adolescent

A version of the RFL inventory that is important to mention is the Brief Reasons for Living adolescent (BRFL-A). This version consisted of 14 items and five factors [38]. The development of the RFL-Adolescent (RFL-A) found 32 overall reasons for living with five main factors. The version of the RFL-A differs in approach by using volunteers to help create the subscales. The RFL-A came directly from a pool of 30 high school students that volunteered to write down specific reasons to live and reasons not to commit suicide. In addition to this, a Masters's level clinical social worker and child psychologist working closely with youth also contributed to the subscale findings [39]. In the study that helped develop the BRFL-A, which was only 14 items, adolescents with moderate to extensive histories of suicidal ideations and behaviors scored lower on the BRFL-A subscales [38].

Gender Differences

When considering the internalized social constructs of gender on an individual's meaning-making, it is not surprising that gender differences repeatedly come to light in RFL studies. One RFL study done in Sweden found that women obtained a higher total score on the RFL, especially on items related to family and children, but scored lower than men on items concerning "what other people" would think (Fear of Social Disapproval: FSD) [40]. One RFL study among young adults found that women scored significantly higher than men on the survival and coping beliefs, responsibility to family, child-related concerns, and fear of suicide subscales [33]. Similar gender differences were noted in an Italian study, with women obtaining higher total scores on the RFL, higher survival and coping beliefs, and the fear of suicide subscales when compared to men, indicating that they were at lower risk of suicide [41]. Women generally indicated higher coping beliefs and considered suicide to be a less acceptable option than men did [41]. Additionally, self-efficacy and RFL were positively correlated and found that when self-efficacy is increased for women, suicide risk decreases. In contrast, increased self-efficacy in men was related to increased suicide risk [41], suggesting the importance of considering the possible impact of gender on suicide risk.

Reasons for Living Translations and Adaptations

The RFL has been translated into various languages and adapted to different cultural contexts. A brief overview of some of these adaptations is discussed to illustrate how the measure can be adapted and effectively used in different contexts, including some of the variations found between groups.

Sweden

A study done in Sweden used the RFL as a buffer against suicide as it has been shown to facilitate coping strategies and positive cognitions among individuals considered to be at risk for suicid [40]. The original RFL was translated to Swedish and administered to a random sample of 1336 Swedish citizens living in the county of Ostergotland. The study found that the Swedish translation of the RFL yielded different results in terms of the subscales from the original RFL, particularly with regard to cultural factors related to the Responsibility of Family and Child-related concerns, which in the Swedish version were collapsed into a single factor [40]. The Swedish translation of the RFL found that some subscales were more or less important when controlling for age differences. Age-dependent variations in RFL scores were noted where MO and FS scores were raised by age [40].

Italy

The Italian version of the RFL was administered to university students (aged 20–26) along with a brief self-report measure to assess suicidal ideation and history of attempts [42]. The six-factor structure of the original RFL was confirmed, and the Italian version of the RFL was able to distinguish suicidal from non-suicidal individuals, similar to the original RFL [42]. Another Italian study administered the RFL along with the Beck Depression Inventory (BDI) and Beck Hopelessness Inventory (BHI) to adults aged 26–65 across the country [43]. This study revealed that Survival and Coping Beliefs (SCB) was the only effective predictor of suicidal intent, with a negative correlation between the BDI and the SCB subscale [43]. Authors suggest that the SCB may be used as a stand-alone measure to assess suicidality, with the rest of the subscales providing ancillary data [43].

Latinx

The original RFL was translated to Spanish (SRFL-I) and found to be analogous to the original RFL in its factor structure and predictive ability [31]. Further analytic study revealed a seven-factor structure which includes Survival Beliefs, Problem Solving Beliefs, Suicide Appraisal, Suicide Self-Efficacy, Family Related Concerns, Moral Objections, and Fear of Suicide [44]. Both Spanish studies found that moral objections to suicide were similarly protective as in English-version studies. Of note, Latinx individuals reported significantly less suicidal ideation and made fewer suicide attempts when compared to non-Latin-x individuals, and scored significantly higher than non-Latin-x individuals on the Survival and Coping Beliefs Scale (SCBS), Responsibility to Family Scale (RFS), and the Moral Objections to Suicide

Scale (MOSS) [45]. Authors stressed that moral objections to suicide and responsibility to family might be particularly protective to Latin-x individuals due to traditionally strong cultural emphasis on religion and family cohesion [44, 45].

China

The RFL was translated to Mandarin and administered to psychiatric inpatients and outpatient clinics. The six factors of the original RFL were confirmed, and similar to the American studies, the subscales Survival and Coping Beliefs (SCB) and Responsibility to Family were predictive of likelihood of future suicide [28]. Authors of this study suggested that endorsement of responsibility to family and children, optimism, and moral concerns by participants who were married, have children, or have religious beliefs, might be important themes to consider in the prevention of suicidal behaviors [28]. The Chinese translation study of the RFL found that religious affiliation did not distinguish those who are suicidal from those who are not suicidal; however, individuals with religious affiliation obtained a higher total score on the RFL than those that were non-religious [28].

India

A study done in Kolkata using the RFL-YA among college students found that three components of reasons for living, coping beliefs, family relations, and future expectation were predictive of suicidal ideation [37]. Furthermore, individuals with fewer personal and social reasons for living were more vulnerable to fostering hopeless expectations when placed under negative, stressful conditions, and crisis situations [37]. The authors proposed that people who possess positive beliefs about their ability to cope with challenging life events are confident about their goal-directed activities, enhancing self-determination and ultimately leading to more hopeful thinking [37]. The study found that reasons for living were positively correlated with hope and negatively correlated with suicidal ideation [37]. Two components of reasons for living, future expectations and coping beliefs, were significant predictors for trait hope and state hope [37].

Summary

This chapter proposes taking a holistic approach to suicide prevention by focusing not only on the cause of psychological pain but also on the strengths inherent to this person and the available resources. The RFL stresses the importance of adaptive rather than maladaptive cognition and assumes that the loss of will to live is the most reliable indication of suicide risk. Some researchers believe that simply completing the RFL can have a protective impact as it prompts the respondent to reflect on the positive aspects of their lives [46].

The original RFL studies found that the Survival and Coping Beliefs, the Responsibility to Family, and the Child-Related Concerns subscales effectively differentiate between suicidal and non-suicidal groups [2]. Generally, individuals who perceive themselves at higher risk of suicide consistently report fewer reasons

for living [35], and those with a history of suicidal ideation tend to score lower on the RFL [38] and the survival and coping beliefs subscale is repeatedly identified as the subscale that is most negatively correlated with suicide [37, 43]. Regarding differences between groups, older adults tend to score higher on the child-related concerns and moral objections than younger individuals do [34], and women have been found to indicate higher survival and coping beliefs and higher fear of suicide than men [33]. Among young adults in India, coping beliefs, family relations, and future expectations were most negatively correlated with suicidal ideation [37], and in the Latinx studies, moral objection and responsibility to family were important in addition to survival and coping beliefs [45, 44]. The Italian [43] and Chinese [28] studies both confirmed the six-factor structure, and both found that the survival and coping beliefs subscale was most predictive of suicide risk. Like the Latinx studies, the Chinese study also found that responsibility to family was significantly protective against suicide [28]. Finally, the Swedish version collapsed responsibility to family and child-related concerns and found that age differences significantly affected moral objections and fear of suicide scores [40].

Not only is the RFL a reliable measure of suicide risk across cultural groups, but it facilitates taking a holistic approach to suicide prevention by considering the strengths and personal, as well as cultural resources, available to someone.

Abstract

In this chapter, we review the background to prevention-oriented risk formulation Pisani et al., Acad Psychiatry 40(4):1–7, 2016 and provide updates about its implementation. Section “The Background: From Prediction to Prevention” begins with a critical examination of traditional approaches to suicide risk assessment which seek to stratify those at risk into categories based on likelihood of future suicidal behavior. Responding to the limitations of such approaches, we set out the criteria for a clinically useful “prevention-oriented” approach. Section “Prevention-Oriented Risk Formulation” outlines a framework for prevention-oriented risk formulation, originally published by Pisani et al. Acad Psychiatry 40(4):1–7, 2016, which seeks to meet these criteria. Since its publication, this framework has gained increasing traction in clinical settings around the world. Section “Updates and Modifications” examines what we have learned from the different contexts in which the model has been applied and how we have modified the model itself and methods for teaching it. Section “Prevention-Oriented Risk Assessment for Violence” then turns to the case for applying prevention-oriented risk formulation to risks other than suicide. Starting with a review of the science concerning co-occurrence of different types of risk, we argue that a unified approach to risk formulation may provide deeper insights into an individual’s risk. At the same time, such an approach also has the potential to streamline the risk formulation process to make its clinical application more efficient.

Keywords

Suicide risk assessment · Violence risk assessment · Risk formulation · Person-centered assessment · Prevention-oriented assessment

Introduction

Section “[The Gold Coast Achievement](#)” describes the successful rapid implementation of the framework across a health care system in Australia. We outline the procedures put in place to promote a paradigm shift in culture and to ensure fidelity using a data-driven continuous quality improvement approach. We then describe the results of this implementation, including a 35% reduction in suicide attempts for those placed on a pathway that includes prevention-oriented risk formulation. Finally, we describe recent efforts to develop an Integrated Formulation that combines risk of violence, vulnerability, and suicide into a single risk formulation process.

We end the chapter by considering the next steps to be taken to strengthen and develop the framework in both scholarly and clinical contexts.

The Background: From Prediction to Prevention

Initial Motivations

For a long time in our field, we have had difficulties with how to synthesize, summarize, and communicate about a person's risk for suicide. Traditionally, a suicide risk assessment has sought to assign a person a level of risk that predicts the likelihood of future suicidal behavior – typically “high,” “medium,” or “low.” Clinicians then select appropriate interventions based on the assigned risk level. However, there are significant problems with both the conduct and the conceptualization of such assessments.

Although risk stratification is necessary in certain contexts, there is a danger that risk categories rather than individual needs will be used to determine the allocation of resources and interventions [6, 51]. The clinician's efforts will thus be channeled primarily into identifying and responding to a risk level, rather than engaging explicitly with the factors underlying suicidal ideation and behavior.

More fundamentally, short-term prediction of suicidal behavior is currently not achievable. And even if future advances enhance predictive power, having better categorization tools will only bring meaningful clinical advances if we have frameworks to contextually anchor risk and to communicate and respond in a personalized way. Many studies have documented that psychiatrists and other mental health professionals are very poor predictors of future self-harm. A recent meta-analysis of 365 studies conducted across 50 years [17] concluded that, “across odds ratio, hazard ratio, and diagnostic accuracy analyses, prediction was only slightly better than chance for all outcomes” and that “no broad category or subcategory accurately predicted far above chance levels.” The authors also found that “predictive ability has not improved across 50 years of research” and thus advocate for new approaches to determining risk that do not rely on traditional risk factors. New technologies and computational approaches that draw on massive datasets from people's lives and records [36, 39] may be able to improve our predictive power in the future, but the traditional distinctions between “high,” “medium,” and “low” levels of risk do not provide a framework for making decisions and communicating about identified risk at an individual level.

A further problem with traditional risk stratification is that risk is dimensional rather than categorical. It is very difficult to find consensus on where boundaries lie between risk levels or to arrive at agreed methods for assigning category membership (e.g., by reference to clusters of symptoms; designations based on self-reports). Similarly, “acute risk,” is variously defined as risk of suicidal behavior “within days,” “within weeks,” or even “within several months.”

Categorization of risk into “high,” “medium,” or “low” assumes that the baseline for comparison is the population as a whole (e.g., “high in comparison to the general norm”), but use of this baseline can obscure important information and limit intervention opportunities. For instance, someone who has just lost their job might be judged

as “low risk” compared to the population as a whole. Yet even if this assessment is accurate, it fails to communicate that the person is at a higher risk than they have ever been before in their life and offers no path to responding to their elevated risk.

A New Approach

Lack of predictive validity, conceptual problems with a categorical approach, and lack of context relevant to the individual mean that standard approaches to suicide risk assessment provide inadequate clinical grounding for therapeutic management plans, and, ultimately, for the prevention of future suicidal behavior [38, 51].

What, then, can we do instead? Carter et al. argue that our goal should be to perform “an individual needs-based assessment followed by intervention to meet patient needs and to reduce exposure to modifiable risk factors” [7], p. 392. In the 2016 paper [34], we suggested that one way of achieving such a goal would be to shift from prediction-oriented assessments to *prevention*-oriented thinking, language, and actions. We identified the following three criteria that a practical approach to risk should meet.

1. Risk formulation should be anchored in the clinical context and patient population in which the assessment occurs [8]. Rates and risk of suicide differ across contexts [22], so clinicians in different practice contexts (e.g., outpatient, inpatient, and emergency services) will have a different experience base with distressed patients and hence different judgments about risk. A patient considered high risk in one context (e.g., a college counseling center) might be considered low risk in another context (e.g., an inpatient psychiatric hospital). These risk appraisals differ, not only because patient populations differ but also because each setting has different resources available for intervention. Likewise, the purpose of an assessment varies by setting. So clinicians must conceptualize and describe risk in relative terms. Describing a patient as “low risk” or “high risk” in the abstract is far less meaningful than describing the patient as at lower or higher risk *relative to other patients in the same context*.
2. Risk formulation should capture the fluid nature of suicide risk in the life of an individual patient [16, 37, 50] and explicitly state the following: (a) how the person’s current risk compares to risk at previous time points, and (b) how risk might change in response to future events.
3. Risk formulation should lead directly to intervention strategies [25]. Data points included should provide the building blocks needed to produce risk management plans.

Source: Pisani et al. [34]

To meet these criteria, we proposed moving away from the identification of risk levels. After some consideration, the language of “risk” was retained, despite its inherently predictive connotation. This language is widely used in clinical settings,

and “risk assessments” are often formal requirements in health and payer systems. Removing all talk of “risk” would thus create insurmountable institutional obstacles to the adoption of a new prevention-oriented approach. Nevertheless, the authors argued that the goal of risk assessments should be reframed. Rather than forming the basis for a predictive determination of risk level, the risk assessment process should instead be understood as the gathering of information that leads to a *formulation* of the individual’s current status. This formulation – a concise synthesis of evidence-based suicide risk data – can then lead to a treatment plan that is tailored to the individual.

Risk formulation is an example of what [5] describe as “structured professional judgement.” A formulation draws on data from a range of sources based on the clinician’s knowledge of suicide risk and then structures this data in a way that contextualizes risk. The goal of a formulation is to understand the patient through past, present, and future, creating a narrative that explains how the person’s current circumstances, behaviors, beliefs, thoughts, actions, etc. have come to be, how they have altered the patient’s life, and how they can be changed or supported in the future. An understanding of a patient’s past and present means we can better plan for the continuation of symptoms, the development of new symptoms, or the eradication/lessening of current symptoms.

This new approach is already impacting the field. As of 2021, the original paper has been accessed more than 24,000 times and has received 73 citations in other peer-reviewed papers. According to Altmetric, it is ranked in the 96th percentile of tracked articles of a similar age. The framework itself has been adopted in many health systems – in some cases at a regional or national level – and empirical data has shown that it can lead to a substantial reduction in suicide risk (see section “[The Gold Coast Achievement](#),” below).

In addition to drawing attention to the need for prevention-based formulation, the paper also offered a method for carrying out such formulations. This method includes the gathering and synthesis of eight categories of data, only two of which relate explicitly to suicide ideation and behavior. Expanding the information base in this way has pushed those working in the field to think more holistically about suicide risk, which has sometimes been identified solely with the severity of suicidal thinking. The introduction of other relevant categories has led to a shift in focus that helps clinicians set reports of suicide ideation or behavior within a contextually anchored picture of the person and their situation as a whole. In addition, the graphical representation of the eight categories in a spatial relationship to risk has allowed for a new perspective on what that risk means for the individual.

One key advance made by this approach is the distinction between “risk status” and “risk state,” terms adapted from the literature on violence risk assessment and management [14]. These contextually grounded categories relate risk to the person’s own particular circumstances at different times and in relation to different groups. Again, the goal when using these categories is not to predict future behavior, but to use these contexts to inform prevention-oriented planning. A second advance is the insistence on the identification of (a) available resources on which the particular individual can draw, and (b) foreseeable changes that are likely to lead to crisis.

Identification of the challenges the specific individual might face and the resources they have available to them steers the formulation toward practical prevention-oriented planning that is contextually anchored in the individual's circumstances.

In brief, the new approach:

- Moves away from a focus on prediction
- Sets aside the determination of risk in terms of stratified categories
- Provides a structure for considering the biopsychosocial dimension of the individual's presentation by considering more than just their current feelings/thoughts
- Distinguishes between risk state and risk status
- Includes within risk formulation explicit attention to what might change in the future to increase risk state (foreseeable changes) and what internal and external resources are available to address risk and aid care planning
- Provides a visual model that is repeatable and can be shared
- Focuses on practical outcomes: the things that might change in a person's life and how the person can be supported through these changes

Prevention-Oriented Risk Formulation

The approach to risk formulation advanced in [34] involves collecting clinical data relating to eight broad categories of information about the individual and their context. This data is then synthesized into a prevention-oriented formulation that can guide planning both to secure the person's safety and to help them get better. The categories fall into two loosely defined classes: those factors that are more enduring and those that are more dynamic. The naming of these categories acknowledges that there are almost no factors that are either entirely static or entirely fluid (Fig. 1).

More enduring factors provide the contextual background for understanding the person and their risk for suicide. They are identified by talking with the person and family members about their personal history and experiences. **More dynamic factors** relate to the present and future and may be subject to faster or slower change. Information about dynamic factors is crucial for helping the clinician identify changes that might result in someone being more or less susceptible to risk.

More Enduring Factors

More enduring factors include the following: (1) strengths and protective factors; (2) long-term risk factors; (3) impulsivity and self-control, including history of substance misuse; and (4) past suicidal behavior and ideation.

Strengths and protective factors. Starting an assessment by gathering information about what makes a person strong and special not only identifies background factors that will be important in understanding how to manage suicide risk, but also helps clinicians to see the person as a unique individual rather than just a case to be solved.

Fig. 1 Risk formulation as presented in [34]

This personal approach is particularly important when working with those at risk of suicide, since responding effectively to suicide risk requires forming a meaningful connection with the person.

Long-term risk factors. These factors provide the historical setting to a person's suicide risk. They are important both because they can guide assessments of relative risk and because they are central to understanding the individual's story – their struggles, burdens, and challenges. When gathering data under this category, it is particularly important to include information on childhood trauma and whether there is a family history of suicide, as well as a mental health history that goes beyond just asking about depressive symptoms. In addition, clinicians will also want to consider demographics under this category. While it is true that certain demographics are at greater or lesser risk than others, this is not the primary reason for collecting this data. Instead, the goal is to understand the challenges a person may have faced because of, for example, their ethnicity or sexual orientation, as this can help a clinician better respond to their needs as an individual.

Impulsivity/self-control (inc. substance abuse). A person's degree of impulsivity reflects the likelihood that they will act without thinking through the consequences. Misuse of drugs or alcohol can have an extremely high impact on impulsivity and judgment and can also impair the person's ability to find alternative solutions to problems. Knowing how likely it is that a person will stop to reflect before taking potentially dangerous actions can both help with understanding an individual's current situation and with planning for the future.

Past suicidal behavior. Information about past suicidal behavior is perhaps the most intuitively obvious data to gather when preparing a risk formulation. However, it is important to remember that, while there is a strong correlation between past and future suicidal behavior, the goal here is not predictive. Rather, knowing the “when” and the “why” of past behavior helps the clinician understand the kinds of situations that may precipitate such behavior in the future. This enables planning to avoid or respond to such situations if they arise again.

More Dynamic Factors

More dynamic factors include the following: (1) recent/present suicide ideation or behavior; (2) stressors/precipitants; (3) symptoms, suffering, and recent changes; and (4) engagement and alliance.

Recent/present suicide ideation or behavior. Again, recent or present suicide ideation or behavior is an obvious starting point. When asking about this category, it is important to pay attention to the feelings that lie behind or accompany the events, so clinicians should also ask about the stressors and precipitants to which the ideation or behavior is a response. Many of the stressors that are correlated with suicide are relatively commonplace events – e.g., relationship breakup or job loss – which most individuals will experience at some point in their lives.

Symptoms, suffering, and recent changes. Often, what turns stressful events into precipitants for suicidal behavior is that they leave the person feeling isolated, like a burden to others, socially defeated or humiliated, and/or trapped, with no way to escape from their painful experiences. Understanding recent changes in such symptoms and suffering – whether they are increasing or decreasing – will play an important role in developing a contextual grasp of a person’s risk and in shaping a risk formulation to make it useful for future planning.

Engagement and Alliance. The final category to assess is a person’s engagement and reliability. This will help the clinician to determine the quality (i.e., accuracy and completeness) of the other data they have collected. This is important not only because it impacts the likely accuracy of the formulation reached when synthesizing the data, but also because it can have significant consequences for safety and treatment planning. For instance, recognizing that there may be significant gaps in what has been shared can help a clinician determine the degree to which a more restrictive environment may be necessary to keep a person safe. Conversely, high engagement and reliability can increase confidence that all details of a safety plan are likely to be followed through. Judging a person’s reliability and openness does not involve a moral assessment of their honesty. Rather, this judgment is simply an important factor in helping the person achieve the best possible outcome.

Risk Formulation

Once all relevant information has been gathered, the next step is to synthesize it into a form that can guide prevention-oriented planning and be communicated easily and

effectively with the patient and other professionals. A prevention-oriented risk formulation will be contextually anchored in the person's history and their current setting. It will not be a static determination but will be sensitive to the changes that are an inherent part of the fluid nature of suicide risk. In particular, the formulation will state how a person's risk now compares to their own risk at different points in time and how it might change in response to the evolving circumstances of the person's life. Most importantly, it will be *actionable*, providing positive guidance toward steps that can reduce risk and move the person toward getting better.

A prevention-oriented risk formulation will include four elements: (1) risk status; (2) risk state; (3) available resources; and (4) foreseeable changes.

Risk status and risk state. Risk status and risk state are two ways of contextualizing risk in relation to baselines specifically chosen for their practical utility. Risk status is risk *compared to whom*, i.e., the individual's risk compared to a given population or setting. Risk status tells us how the person's risk relates to the healthcare setting they are in, or to the setting they have come from or may be transitioning into. For instance, we might say that John is at considerably higher risk than most of the other people in the primary care setting in which he is being assessed. This can help guide a decision that he may be cared for more appropriately in a specialist setting in which most of those being treated have a risk level that is similar to his. Risk state is risk *compared to when*, i.e., relative to the person's own risk at other times. For instance, Peter may have a low risk status relative to a given population but still have a high risk state relative to his own past history. Knowing this can help the clinician see that Peter may need more support now than he did previously, allowing support plans to be framed accordingly. In comparison to simple risk stratification, risk status and risk state allow responses to risk to be tailored to the circumstances of the individual.

Available resources. Available resources can often be identified by reflecting on the strengths and protective factors noted when gathering data about the at-risk person. However, it is important to remember that not all protective factors will be available resources on which a person can draw directly when in need (e.g., having children in the house is a protective factor but not a resource that someone can access specifically in response to a change in their situation). Available resources can either be internal resources, such as a person's ability to process feelings or solve problems, or external resources, such as a good friend or an AA sponsor who is committed to the person's sobriety and well-being.

Foreseeable changes. Foreseeable changes are the types of events that might happen or circumstances that might arise which have the potential to increase risk rapidly. By drawing on a person's history and context to identify changes that might precipitate a crisis, the clinician can work with the person proactively to develop safety plans that will respond to these specific situations. For instance, Rob tried to end his life after finding out that his wife was having a relationship with another man. A foreseeable change identified by the team that treated Rob in the ED was the possibility that Rob's wife, Louise, might decide to leave him. When Rob and Louise engaged in marital therapy, the therapist was made aware of the ED's risk formulation, including the foreseeable changes. Rob was optimistic that trust could be rebuilt, and Louise insisted that she had no intention of leaving. However, to build

a plan around the foreseeable change, she agreed that she would inform the therapist first if she did decide to leave. When Louise ultimately did decide to leave, she acted in accordance with the contingency plan and told Rob in the therapist's office, so Rob had immediate help on hand to ensure that he was supported through the moment of crisis.

When identifying foreseeable changes, the clinician should pay particular attention to the data gathered under "Stressors/Precipitants" to pinpoint scenarios that may leave the person feeling as if they have no control of events, are isolated, humiliated, trapped, and/or a burden on others. In developing a risk formulation, the clinician should identify at least two foreseeable changes to address in the person's safety plan.

Updates and Modifications

Since the initial publication of the prevention-oriented risk formulation approach in 2016, a range of improvements and developments have emerged from ongoing research. In addition, tens of thousands of health care workers have now received training that includes exposure to risk formulation. This adoption has both increased confidence in the usefulness of the approach and has allowed for the delivery system to be refined in response to direct feedback, with the goal of facilitating the clinical understanding and application of the framework.

A. Embedding Risk Formulation Within a Broader Framework for Recovery-Oriented Suicide Prevention. A major development has been the embedding of risk formulation into wider frameworks for recovery-oriented suicide prevention. This has been attempted in various ways in different settings and countries around the world. One such framework has its origins in Pisani's work with a wide range of organizations to transfer research from academic settings to live healthcare contexts. This framework was first introduced in New York State and has since been rolled out at the regional and national level in health systems across the USA, Australia, and New Zealand.

The SafeSide Framework supports the gathering and synthesizing of data and then defines steps for responding to the formulation with safety planning and interventions as appropriate, and then extending care and support beyond the immediate healthcare context. The core tasks of the framework (Connect-Assess-Respond-Extend) act as a map of best practices that provides health systems with a common language and consistent structure for approaching suicide prevention.

- **Connect.** Involves asking directly about suicide and about the person's story and experience. The goal is to form a meaningful and collaborative connection with the person so that the clinician and the at-risk individual can work together toward the person's safety and future well-being. This connection is foundational for the successful gathering of the data that inform the risk formulation.
- **Assess.** This core task involves gathering data under the eight domains discussed above and then synthesizing this information into a risk formulation.

- **Respond.** The respond core task covers the specific actions, plans, and resources identified as appropriate for the person at risk and for others in their lives. This includes how best to work as a team to provide and document the care that is delivered.
- **Extend.** Focuses on extending the impact of care beyond the individual and beyond the specific healthcare setting in which they initially receive it. This gives additional confidence that plans and treatments will continue to have a positive impact on the person's life in the long term. Steps taken to extend care can range from ensuring a warm handoff when making a referral to the use of empirically validated techniques such as nondemand caring contacts.

B. Conceptual Evolution of Risk Status and Risk State. Feedback on the presentation of risk status and risk state has led to a number of clarifications.

The presentation of the elements in the original diagram led some clinicians to assume a linear connection between more enduring factors and risk status, on the one hand, and more dynamic factors and risk state, on the other. To avoid this misunderstanding, we have removed the shading that appeared to identify these as fixed connections (as seen in Fig. 2, below).

A confusion sometimes arose from the use of the language of “populations” in the description of risk status as “risk relative to others in a stated population.” While many found this phrasing helpful, the term acted as a barrier in other cases because it evoked epidemiological language for some trainees. This led some clinicians to question their ability to make judgments if they did not know the suicide risk rates for a given group, while others were uncomfortable with their ability to formally define a given population. After experimenting with different wording in training sessions over several months, Pisani settled on “Risk relative to others in a given setting (current or being considered).” This phrasing led both to greater clarity about how to use the framework and to fewer questions about how to select a “population” with which to compare the person. Although level-of-care decisions are not the only kinds clinicians need to make, they are decisions that need to be made often. Being able to say, “This person is at higher risk than anyone else we have seen in our clinical setting in the last three months” provides a clear way of understanding and communicating how a person can be helped. Conversely, if someone in inpatient care is at a lower level of risk than is typical among such patients, and is at a level of risk that is similar to that of other people typically referred to the outpatient service, then that is a good sign they may be ready for discharge.

In addition to, or instead of, using a person's current or prospective setting for the comparison to determine risk status, other reference groups can usefully be selected. It is often the case that making *multiple* comparisons will help the clinician to understand and explain the situation of a particular person. For instance, we might want to say to someone, “The current risk you're facing is more than we feel we can support you with safely just with you coming here every few weeks and keeping in touch by phone. On the other hand, the risk isn't at the level where we would normally think a hospital might be an appropriate setting. So, as we have found with other people in a similar situation, what we think would work best for you is to have

Fig. 2 A framework for recovery-oriented suicide prevention

an outreach team visit regularly with you and your family for the next six weeks to provide you with some additional support.”

Some clinicians found making comparisons with other people they work with uncomfortable when talking to an at-risk person. A common worry was that such a comparison could be dispiriting if it was understood as implying that the person was worse off than many others. To avoid running this risk, Pisani now advises framing these comparisons in terms of the appropriateness of the match between what a person is going through and the supports that would typically be offered in a given setting (“We feel that the current setting doesn’t offer enough support for someone in your position”). Approaching the language in this way enables clinicians to avoid direct comparisons to other people while still conveying the same clinically useful information.

Finally, to make it clear that risk status is not just a new term for “chronic risk,” additional emphasis is now placed on the goal of anchoring the risk in a context that facilitates communication, drives decisions, and nudges the individual and system toward greater transparency.

C. Emphasizing the “Why” Over the “What.” An important point that was not stressed in the original article is that the “why” that lies behind someone’s suicidal behavior or ideation is more important than the “what.” This means that the reasons a clinician identifies for assessing that risk state is higher now or risk status is similar to others supported in a given setting are at least as important as the assessment of the state/status itself. This is because the formulation is primarily a tool aimed at prevention, communication, and making the thinking behind decisions transparent. Saying that someone is at “higher risk than X” gives a clinician less to work with in relation to these goals than does grasping the reasons *why* this is the case. The reasons identified will be specific to the person and are more likely to be useful in planning and prevention than just knowing whether someone’s risk is at a higher or lower status or state.

D. Moving Beyond the Prediction/Prevention Polemic to a Greater Emphasis on Personalization. The 2016 article had a polemical goal: to argue that a focus on categorical stratification was unhelpful for communicating about suicide risk and informing preventive responses. This was framed in terms of a shift from prediction to prevention. With more experience, and with the broad adoption of our formulation model in everyday practice, polemical focus has since diminished in our work.

We now see risk stratification and the endeavor to develop predictive models as two separate issues. Risk stratification has to do with the attempt to categorize who is at greater risk and to allocate resources accordingly. While studies continue to confirm problems with stratification (e.g., Wyder et al.), we also accept that some degree of stratification is inevitable when seeking to manage limited resources and when assigning people to pathways according to their relative needs. In addition, we have seen that organizations do not, in practice, need to completely reject stratification if they are to successfully adopt the type of risk formulation we advocate: Formulation can, for instance, live alongside the use of stratification when it is required in certain types of documentation.

Although our article emphasized the futility of rigid categorization in the face of a lack of predictive capability, this has sometimes been misunderstood as a rejection in principle of research into potentially useful predictive techniques. In fact, with more advanced technologies and the ability of machine learning algorithms to parse very large numbers of variables, it is possible that our capabilities in this field may advance significantly in the future. Of course, if this happens, we will still need a framework for thinking through and contextualizing this data. However, a commitment to risk formulation does not imply a rejection of the search for better data to inform our assessments.

Updates to the Model Since 2016

- Risk formulation embedded into broader frameworks for recovery-oriented suicide prevention
- Evolution of conceptual presentation of risk status and risk state
 - Revision of diagram to avoid suggestion of fixed connection between a) more enduring factors and risk status, and b) more dynamic factors and risk state.
 - Change in language from “risk relative to others in a stated population” to “Risk relative to others in a given setting (current or being considered).” Encouragement to use multiple comparisons.
 - Rather than make comparisons to other people, clinicians have the option of making comparisons between a person’s needs and the levels of support offered in different settings.
 - Additional emphasis placed on anchoring risk in context that facilitates communication, drives decisions, and nudges individual and system towards greater transparency.
- Emphasizing the “Why” over the “What”
- Moving beyond the prediction/prevention polemic

Prevention-Oriented Risk Assessment for Violence

Many clinicians who adopted the prevention-oriented risk formulation for suicide were quick to ask whether the process might be expanded to address violence risk. The reasons for this question are straightforward. First, many clinical contexts require assessments of both types of risk, whether due to internal clinical policies and procedures, or to broader legal requirements. Indeed, conditions described using phrases such as “danger to self or others” are common bases for involuntary civil commitment to psychiatric facilities in the USA and other countries. Second, maintaining entirely separate approaches to assessing risk for violence and risk for suicide seems inefficient. After all, clinicians will explore many of the same domains (e.g., substance abuse, impulsivity, resources, coping strategies, etc.) to inform each assessment and might consider many of the same interventions to prevent either type

of harm. Might there be a way, clinicians asked, not only to efficiently gather the data needed to consider both types of risk, but also to approach violence risk with a prevention-oriented model?

Like the field of suicide risk assessment, the field of violence risk assessment has long struggled with an overemphasis on prediction, imprecise risk categories, and other similar challenges. Yet those working in some areas of the field, primarily within forensic psychology, often acknowledge many of the limits to prediction-focused models and have consequently moved toward distinguishing between violence-prediction approaches and those that focus on violence risk management [21]. There are, thus, good reasons to think that the fields of violence risk assessment and suicide risk assessment may be mutually informative, and that emerging practices in one may also be applicable to the other. For example, the explicit distinction between risk status and risk state – a key element in the prevention-oriented suicide risk formulation model – was drawn from emerging best practices in violence risk assessment [14].

In short, there are strong conceptual reasons to think that both violence risk assessment and suicide risk assessment should move toward more prevention-oriented approaches. There is also a strong scientific basis for thinking that clinicians should simultaneously consider both the risk of violence and the risk of suicide.

Scientific Basis

Put simply, self-harm and harm-to-others often co-occur, and each form of harm is a risk factor for the other. Data supporting this conclusion have been drawn from a variety of methods (e.g., comprehensive reviews, population-based studies, individual samples, etc.) and populations (e.g., clinical and nonclinical, adolescent and adult, etc.). While a comprehensive literature review is beyond the scope of this chapter, it will be useful to consider a number of illustrative key findings.

In a systematic literature review of 123 studies, violence and self-harm were clearly associated with greater aggression in self-harming populations and greater self-harm in aggressive populations when compared to control groups [31]. The researchers emphasized that this finding was robust across population, setting, measures, and data collection methods. They concluded that engaging in one behavior increases the chance of engaging in the other, and thus patients referred for suicidality should be screened routinely for their risk of violence as well.

An influential single-sample study reached similar conclusions. The MacArthur study of violence and mental disorder [26, 44] is considered the most comprehensive and exhaustive study of violence and mental disorder, the “gold standard” study underlying modern violence risk assessment. In a follow-up to the original study sample, researchers examined 951 psychiatric patients and found that violence against others, violence against self (self-harm), and being a victim of violence (victimization) were highly co-occurring [28]. A total of 30% of the sample had engaged in both self-harm and harm to others, and the vast majority

of these had experienced violence from others as well. The authors concluded that “given the substantial overlap among the three forms of violence, clinicians should routinely screen patients who report one form for the occurrence of the other two” [28], p. 516.

In a population-based longitudinal cohort study of nearly 2 million young (age 15–32) Swedish citizens, researchers identified those who received clinical care for deliberate self-harm (3% of the total sample) and considered their risk for subsequent violent crime [40]. Those who had received clinical care for self-harm were far more likely (i.e., a five-times higher crude hazard ratio) to be convicted of a violent crime than those who had no known instances of self-harm. Even after adjusting for psychiatric comorbidity and environmental factors, self-harm was still associated with violent crime, and this relation was particularly strong for women. On a practical level, the authors concluded that “the risk of violence, as well as the risk of suicide and self-harm, should be assessed among offending and self-harming individuals” (p. 615).

Another study of the general population underscored the co-occurrence of self-harm and harm to others. In data from the US National Epidemiologic Survey on Alcohol and Related Conditions-III (NESARC-III), which included several questions related to self-directed violence and other-directed violence, 4.4% of the adult population endorsed self-directed violence, while 2.8% endorsed *both* self-directed and other-directed violence [20]. Substance abuse and psychiatric disorders were more common among those who endorsed both forms of violence, as compared to those who endorsed either one or neither. Personality disorders (particularly antisocial and borderline personality disorders) were most strongly associated with the combined category of violence. Once again, researchers concluded with practical guidance: “Clinicians are advised to explore homicidal risk among patients who attempt suicide or who have suicidal ideation and, conversely, assess suicidal risk among patients who report violence” (p. 391).

Of course, even without such explicit guidance that one type of harming behavior should prompt clinicians to assess for the other type, an exploration of relevant risk factors may lead clinicians to consider both types of risk. Researchers have long noted the substantial overlap among the risk factors for violence and suicide and even speculated that these may reflect a shared propensity for impulsive aggression [1, 23, 35]. Knowing, for example, that a patient tends to act impulsively, drink heavily, and react strongly to fears of abandonment should probably prompt a clinician to consider that patient’s risk for violence *and* suicide, and to take steps to mitigate both risks, even if the patient is known *only* to have previously been aggressive toward self *or* aggressive toward others. Finally, an obvious, explicit threat of one type of behavior should prompt consideration of the other. Researchers recently concluded that “threatening homicide was . . . a novel predictor of suicide risk” [3]. That is, among a unique sample of “threateners,” known to the health and/or justice systems for threatening to kill a person other than themselves, half of those who died in the follow-up period died by suicide (more than any other cause). Threateners were more likely to kill themselves than to kill others [48, 49].

Practical Basis

In light of the strong scientific basis for considering suicide and violence risk together, it is reasonable to reflect on the practical rationale as well. Certain rationales, mentioned earlier, are obvious. Concerns about violence arise in many of the same contexts as concerns about suicide: psychiatric hospitals, community clinics, and even schools. Many health care settings already *require* clinicians to address both types of risk in their intake assessments and documentation. Either type of risk may provide a basis for involuntary hospitalization. Given that the risk factors for each type of risk overlap to such a significant extent, assessing these risks through separate processes may be inefficient and unnecessarily duplicative. Conversely, assessing both risks in a complementary manner offers the chance of not only greater efficiency, but also greater insight, given the possibility that each type of risk will cast light on the other when considered together.

There may also be a number of less obvious advantages to the integration of violence risk assessment into a combined prevention-oriented risk formulation. Violence risk assessment is “a required professional ability for every clinical psychologist” [19], p. 928, and most other mental health professionals, just as is suicide risk assessment. Yet violence risk assessment is not a standard component of most clinical training programs, and most clinicians in routine practice have had little, if any, formal training in violence risk assessment or management [4, 24, 41]. Psychiatry textbook sections addressing violence risk typically mention commonplace, static risk factors for violence (e.g., young age, male sex) and instruct clinicians to ask about violent ideation [36, 39], but this guidance stops far short of a detailed approach to risk formulation. To be clear, there exists extensive research and training on violence risk assessment, but these have rarely spread beyond the professional specialties of forensic psychology and forensic psychiatry, and the related discipline of threat assessment. These fields have developed a rich literature addressing base rates of violence and risk factors for violence, as well as tools and practices to assess the risk of violence (for summaries, see [8, 21, 32]). However, these resources are more often used in the context of forensic facilities and formal forensic evaluations that allow for ample time to conduct extensive record review and collateral interviews, which clinicians in routine clinical practice settings (e.g., busy community clinics) may be less able to perform. In short, nonforensic clinicians in routine practice settings usually lack substantial knowledge of violence risk assessment and thus default to unstructured prediction-type approaches. Many would greatly benefit not only from a basic literacy in the fields of violence risk assessment and threat assessment [29], but also from a prevention-oriented approach that can be integrated into routine clinical practice.

Therefore, the integration of a violence risk assessment approach with a well-established prevention-oriented suicide risk assessment approach may allow for richer consideration of the risk-relevant data that may be less fully or formally considered in standard, default approaches to violence risk. This sort of integration would also address the need in violence risk assessment, as in suicide risk assessment, to move beyond prediction. When the goal is violence *prevention*, the aim

becomes not only an overall risk estimate, but rather, ongoing identification and mitigation of any factors that may be conducive to violence or that may suggest a patient is progressing toward violence, as well as strategies to collaborate with the patient and others in these efforts (see [29]).

Process

In our view, the prevention-oriented risk formulation model for suicide, first advanced in [34] and since modified as described in section “[Updates and Modifications](#)” above, lends itself well to facilitating a similar assessment of violence risk. Given the substantial overlap in the risk factors for violence and for suicide, much of the clinical data-gathering process is the same. Thus, “adding” a violence risk formulation is less a matter of conducting a second assessment, and more a matter of considering much of the same data (with a few additions) in light of its potential relation to violence as well as suicide. Indeed, so closely aligned are the factors that we were able to develop a supplemental module on violence risk formulation and easily integrate it with a training program developed for suicide risk.

Of course, there are a few additional elements that are crucial when considering violence risk. The most obvious is eliciting a detailed history of prior violent behavior. Although identifying past violence is also prioritized in predictive models – based on the strong empirical relation between past violence and future violence – the goal here is to understand not just the occurrence, but the context, antecedents, motivators, and consequences of the violence. While asking explicitly about violence risk may seem self-evident, clinicians are often reluctant to do so. We thus urge all clinicians to *ask questions specific to past violence*, just as they would ask about past suicidal behaviors. Such questions include a thorough review of all past instances of violence.

Eliciting information about past violence is essential to understanding the contexts and situations in which the patient would most likely commit violence in the future. These details not only help inform assessments of risk status, but also inform both the “foreseeable changes” later in the model and strategies to extend care. We also encourage clinicians to ask about instances in which the patient was nearly violent but did *not* proceed with violence. These instances may provide clues to patient strengths and resources, as well as risk-management strategies a clinician can use later.

Example Questions for Reviewing Past Violence

- What was the nature, type, frequency, and severity of the violence?
- Who were the past victims?
- What was the context or setting for the violence?
- What events preceded and followed the violence?

(continued)

- How recent was the last instance of violence?
- Is there any evidence of escalation of violence?
- Were there incidents in which the person was nearly violent but did not proceed with the violence?

Beyond considering past violence (or near-violence), other clinical data to be gathered generally follows that summarized in the prevention-oriented suicide risk formulation model [34] and in Fig. 2. As in the case of suicide risk, it is important to consider impulsivity, self-control, substance abuse, and mood, as well as “symptoms, suffering, and recent changes.” Some clinical conditions – such as paranoia and irritability or anger – may bear a stronger relation to risk of violence than risk of suicide. Although psychiatric symptoms are a primary focus for clinicians, clinicians must also consider the much broader range of (nonpsychiatric) risk factors for violence. As Monahan and Steadman emphasize, “A person with serious mental illness – *even one that bears a causal relationship to violence* – may have a high (or low) overall likelihood of violent recidivism for reasons independent of their illness” ([27] p. 247). Thus, clinicians should consider carefully “stressors and precipitants” that may be less psychiatric in nature, and more related to relationship conflict, loss of status, and perceived provocation.

As in the application of the original model to suicide risk, in the assessment of violence risk we emphasize the distinction between *risk status* and *risk state* (this distinction was, itself, originally drawn from the violence risk literature; see [14]). Risk status involves *a patient’s risk of violent behavior relative to others in a particular population or context*. Some patients remain at higher risk status and warrant closer risk monitoring for long periods of time because of unalterable historical characteristics, such as past violence or early onset violence. In contrast to risk status, *risk state* refers to a person’s *current* violence risk compared with their own risk at baseline or prior points in time. In other words, *risk state* involves the “individual’s propensity to become involved in violence at a given time, based on particular changes in biological, psychological, and social variables in his or her life” ([14], p. 349).

Therefore, assessing risk state involves a focus on current clinical status. Are there changes in the psychiatric symptoms that seem most relevant to violence risk? Is the patient increasingly abusing substances? Has conflict with family escalated? In many ways, these are the types of tasks with which clinicians are already most comfortable – assessing improvement or decline in clinical functioning and intervening appropriately. But clinicians must be comfortable considering these clinical changes as they relate to violence potential, and explicitly discussing with patients the prospect of violence.

As with the suicide risk formulation, *available resources* are a crucial focus. The identification of internal or social strengths on which the person can draw to help mitigate their risk of violence is an essential aid for safety planning. Likewise, identifying *foreseeable changes* that are liable to increase risk or precipitate a crisis

can help in shaping a safety plan that responds directly to the circumstances that are most likely to lead to violence.

Fairly recently, violence risk scholars have begun recommending “scenario planning” [15], a similar concept in that it involves identifying the most likely changes or scenarios that may leave a person more inclined to act aggressively, based on their particular risks and vulnerabilities. Identifying foreseeable changes, or conducting scenario planning, may involve identifying potential victims. In contrast to suicide risk formulation, in which the potential victim is obvious, violence risk formulation must consider the person(s) at risk of harm. This may involve clearly identifiable victims (e.g., a spouse or partner in situations marked by relational conflict or violence; an individual toward whom the patient has a grievance), but it also may involve potential victims unknown to the patient, but at risk due only to proximity or chance.

Indeed, the need to consider victims illustrates one of the challenges to prevention-oriented risk formulation that may be greater with violence than with suicide. Although both outcomes can be impulsive, many types of violence are even less deliberative than suicide, reflecting greater impulsivity and more immediate contextual influences: Consider the man who is intoxicated in a bar and responds aggressively to another angry and provocative patron, or consider the psychotic woman who misperceives a stranger’s innocuous behavior in ways shaped by her paranoid delusion. We acknowledge that it is likely impossible to plan for *all* foreseeable changes, risky contexts, or potential victims. But as with suicide risk formulation, the goal is to identify the primary, or most likely, types of changes (e.g., losses of support, status, or protective factors; increases in substance abuse or particular symptoms) that would contribute to violence.

Conclusions and Future Directions

Integrating a prevention-oriented violence risk formulation into the suicide risk formulation has strong conceptual and practical appeal. Accounts from GCMHSS of steps taken to develop an “Integrated Formulation” (described in section “[The Gold Coast Achievement](#),” below) suggest that it may be practically feasible to bring these elements together in ways that improve both efficiency and comprehensive care.

Of course, much work remains to be done. Recent moves toward integrating violence and suicide risk formulation will require study from a variety of perspectives, addressing both the feasibility of implementation and the potential outcomes.

The Gold Coast Achievement

Rapid Implementation of Prevention-Oriented Risk Formulation

In 2016, Gold Coast Mental Health and Specialist Services (GCMHSS), in Queensland, Australia, rapidly implemented prevention-oriented risk formulations into routine clinical practice across the entire mental health service. GCMHSS is a public

mental health service serving all age groups across a population of approximately 600,000. It provides inpatient and community care and supports one of the busiest emergency departments in the country.

The implementation of prevention-oriented risk formulation occurred within the context of the broader implementation of a Zero Suicide framework within the service (see Table 1, below), with high fidelity to the seven core elements of leadership, training, identify, engage, treat, transition, and improve [9, 46].

The leadership component of the Zero Suicide framework underpinned a shift in the mindset on a range of topics, which spread from service leadership to staff at every level. This change in perspective led to (1) a growing understanding of the limitations of a categorical risk prediction approach; (2) a move away from using diagnosis as a gateway to treatment; (3) the introduction of suicide-specific interventions; and (4) a shift in culture that aspires to the elimination of suicide in consumers (the GCMHSS terminology for “patients”) under care. At the same time, the Zero Suicide framework led to the embedding of a restorative Just Culture that supports consumers, families, clinicians, and the organization as a whole in feeling safe. This developing culture challenges nihilistic views about suicide prevention efforts and engages staff actively in understanding that, although we cannot predict suicide risk, we can improve safety and well-being through a systems approach to suicide prevention.

A Restorative Just Culture

Incident review processes should align with principles of a Restorative Just Culture, which focuses on forward looking accountability and the avoidance of blame, and supports a healing, learning, and improvement process.

Restorative Just Culture

- replaces backward-looking accountability with a focus on the hurts, needs and obligations of all who are affected by the event.
- asks: Who is hurt? What do they need? and Whose obligation is it to meet those needs?
- promotes the healing of trust, relationships, and people and empowers first and second victims.
- moves away from asking *who* did something wrong and what should be done about them, to *what* was responsible for things going wrong and how this can be addressed.
- accepts that involved staff can have both accountabilities and needs, and is predicated on the principle of inclusive engagement of all stakeholders.
- is action oriented, assigning roles and responsibilities for all who have a stake in the event.

Adapted from: “Inconvenient Truths in Suicide Prevention: Why a Restorative Just Culture should be implemented alongside a Zero Suicide Framework,” Turner et al. (2020).

Table 1 Elements of Zero Suicide framework, associated goals, and steps taken by GCMHSS in achieving those goals

ZSF element	Goal	Steps taken at GCMHSS
Leadership	Create a leadership-driven, safety-oriented culture committed to dramatically reducing suicide among people under care. Include suicide attempt and loss survivors in leadership and planning roles	Engagement of all stakeholders through a clinical redesign process Challenging the status quo and current culture; introducing new ideas Review of models of Just Culture
Train	Develop a competent, confident, and caring workforce	Training identified and modified to be specific to the clinical pathway of care to be implemented within the service. Supervision and support provided to assist embedding training into practice
Identify	Systematically identify and assess suicide risk among people receiving care	Development of the clinical pathway of care (Suicide Prevention Pathway)
Engage	Ensure every person has a pathway that is both timely and adequate to meet their needs. Include collaborative safety planning and restriction of lethal means	
Treat	Use effective, evidence-based treatments that directly target suicidality	
Transition	Provide continuous contact and support, especially after acute care	This overlapped with the pathway of care and focused on transitions of care Strengthening connections with the broader community and partnership with the Primary Health Network
Improve	Apply a data-driven quality improvement approach to inform system changes that will lead to improved patient outcomes and better care for those at risk	Development of a Research and Evaluation Strategy Review of responding to and learning from suicides with a focus on embedding new practices that aligned with Restorative Just Culture principles

The systems approach taken by GCMHSS included the development of a clinical pathway of care (the Suicide Prevention Pathway, or SPP) which built on existing skills and approaches to the assessment of and engagement with the consumer. The goal here was to include support for clinicians to improve their skills in the exploration of suicidal intent through the use of Shawn Shea's "Chronological Assessment of Suicide Events" (CASE) model and in the use of the prevention-oriented risk formulation [42]. This approach provided support for a move away from categorical risk prediction. Instead, staff focused on understanding individual and contextual factors that could support the development of an individualized care plan, safety planning interventions (including counseling on access to lethal means and consumer and family education), and rapid follow-up into the community with warm handovers of care. Importantly, the systems

approach also includes tailored training to support all components of the pathway, including cultural and mindset shifts, and has a strong focus on data-driven continuous quality improvement.

As part of the implementation of this framework, deliberate efforts were made to engage clinicians right across the organization. The initiative included face-to-face discussions between the leadership of the service and all mental health teams, enabling stakeholders to explore these important cultural and mindset shifts, as well as the opening up of working groups to all clinicians via expressions of interest. These working groups contributed to the development of the pathway and the training needed to support its implementation.

When the SPP was initially being developed in early 2016, there was a lack of guidance in the literature regarding how to support staff in moving away from categorical risk prediction approaches, and the statewide electronic medical record forms continued to expect the use of the terms “high,” “medium,” and “low” to denote risk levels. The publication of [34] provided a potential solution to this issue. GCMHSS contacted Pisani, who provided guidance on the use of the prevention-oriented risk formulation. Pisani also provided training videos initially developed for a study that examined educational outcomes in primary health care [13, 33].

Building on the completion of the Suicide Prevention Pathway and the work already underway across the service to actively engage clinicians in this cultural shift, the service collaborated with the Queensland Centre for Mental Health Learning to adapt their training for Suicide Risk Assessment and Management in Emergency Departments. This training included both online (3 h) and face-to-face (1 day) elements and was updated to include training in prevention-oriented risk formulation, safety planning interventions, the SPP, and the philosophy of the Zero Suicide approach.

For planning purposes, following the engagement of clinicians across the service, a start date was selected for the SPP. This provided a target to work toward for the training of all medical staff and community staff (including those inreaching into the two emergency departments). As a result of competing demands stemming from the need to implement a change mandated by the statewide Mental Health Act, inpatient staff training was postponed to a later date. A roster of senior staff and educators was created to support the rollout, including through the provision of support across all shifts for a two-week period from the time of commencement of the new pathway. These staff provided coaching on and modeling of the application of new skills, including the use of the prevention-oriented risk formulation. Resources such as flowcharts and example formulations were printed and placed in all workplaces, as well as being made available online. An evaluation plan was developed that included a data-driven continuous quality improvement approach to embedding the new processes.

The training program initially used a “train the trainer” model, with a range of staff across the service being trained to disseminate the new practices. However, practical experience and new research on the train the trainer model [10–12, 18] and practical experience both drew attention to the severe limitations of this approach. Over time, it became clear that the most effective means of reliably delivering the

training was to use two experienced senior clinical staff members with training expertise and dedicate time to train the vast majority of staff across the service.

The Acute Care Team, who saw most of the consumers being placed on the SPP, faced some challenges during the initiation of the pathway. These were likely the result of a period of increased demand that coincided with the slowing down of processes as staff became familiar with the new approach and efficient in its deployment. These teething problems lasted for approximately 2 weeks, during which period a number of clinicians from across the service volunteered some of their time to support the team until the challenges were resolved.

An evaluation plan included the identification of all consumers placed on the pathway and measurement of fidelity to the core components of the pathway. This process included a manual review of electronic medical records (EMRs) to determine whether the components were being completed both in full and correctly. For example, for the prevention-oriented risk formulation, information was gathered to determine whether all components were being commented upon and whether terms such as “risk status” and “risk state” were being used correctly. The data gathered was then fed back to teams, including through the use of communiques which outlined areas of strength and reminded clinicians of processes in cases in which confusion or gaps were identified in the EMRs. The communiques also provided links to training that reinforced the SPP components. The pair of clinicians who provided the bulk of the training then provided further in-services and top-up training to teams who identified gaps in their performance. One familiar theme in the early implementation of prevention-oriented risk formulation was a degree of confusion around the terms “risk status” and “risk state,” so clarification of the meaning of each was a focus of the ongoing training.

In addition to a data-driven continuous quality improvement approach to drive ongoing improvement, sustainability across the system continues to be supported by the embedding of the training as part of the mandatory training expected at orientation for all new staff.

Results. As part of the evaluation process, an audit was undertaken of all consumers presenting with a suicide attempt pre- and postimplementation of the Suicide Prevention Pathway (including prevention-oriented risk formulation). Comparing March and April 2015 ($n = 132$) and March and April 2017 ($n = 95$), there was very strong alignment with a categorical risk prediction approach prior to the implementation, seen in the use of the terminology of “high,” “medium,” and “low” (88.6% using the categorical risk prediction approach in 2015; the majority of consumers in 2015 were rated as either low (58.3%) or medium (25%) risk). Following implementation of the pathway, there was a rapid move away from categorical approaches to prevention-oriented risk formulations (5.3% using a categorical risk prediction approach in 2017).

Fidelity to the prevention-oriented risk formulation for those placed on the pathway has continued to be tracked over time, with feedback provided to the teams. Fidelity to the formulation was reported across 2017 to 2019 and maintained levels over 80% [46]. Evaluation of the impact of the Suicide Prevention Pathway with its embedded prevention-oriented risk formulation has been undertaken,

demonstrating that the pathway is associated with a 35% reduction in suicide attempts for those who are placed on it [43]. Determining which components of the pathway have the greatest impact on these positive outcomes is the subject of further important work.

Conclusion. Prevention-oriented risk formulation was embraced by the GCMHSS as a solution to the dilemma of how to support clinicians in a move away from unhelpful paradigms of categorical risk prediction approaches. The available data shows that risk formulation was rapidly adopted, and clinicians have maintained a high fidelity in its use across multiple years. The implementation was supported by addressing cultural and attitudinal factors, and then supporting staff through both initial and ongoing training, including the provision of training in multiple modalities, such as online, in person, update communiques, and flowcharts for the workplace. The provision of high-quality data has assisted not only in evaluation of the Suicide Prevention Pathway, but also in a continuous quality improvement process which has seen sustained high fidelity to its use.

Developing and Implementing an Integrated Formulation

GCMHSS had significant success in rapidly embedding prevention-oriented risk formulation with good fidelity into routine practice within a Suicide Prevention Pathway. However, there was less evidence that risk formulation was being used as a routine practice for consumers who were not placed on the pathway. In addition, a number of issues were identified that required attention in order to further embed the Suicide Prevention Pathway and to mitigate any unintended consequences.

The following issues were among those identified:

- Consumers rarely present with just one domain of risk; those with suicide risk frequently also have risk for violence and/or vulnerability as well. Vulnerability includes a broad range of considerations, such as domestic and family violence, financial vulnerability, impaired decision-making, sexual disinhibition, and vulnerability to exploitation. There are complex and multidirectional relationships between these various domains of risk, including significant overlap between risk factors for both violence and suicide (discussed in section “[Prevention-Oriented Risk Assessment for Violence](#),” above). Risk factors such as past trauma, lack of social supports, sexual disinhibition, and cognitive impairments can increase vulnerability and other domains of risk. Some specific subpopulations, such as the recently incarcerated, may have increased risk in all domains. Using one process for suicide and different processes for other risks would lead to duplication and inefficiency for busy clinicians in our acute settings and would represent a potential missed opportunity to understand the interaction between risk domains.
- A risk-screening tool was already in use at the state level throughout Queensland, and it was felt that there was a need to further clarify how this screening tool and the recently implemented prevention-oriented risk formulation related to one another.

- In line with the Zero Suicide framework, a focus of the suicide prevention efforts occurring in the service was a move away from using diagnosis as a “gateway” to care and toward ensuring suicide-specific interventions. However, it was also important to diagnose and intervene in cases of mental illness, substance use disorders, physical health issues, and other issues when present, and it was felt that there was, at times, an underarticulation of mental illness and co-occurring disorders.
- It was recognized that formulation in general is an essential component of comprehensive care. Formulation takes a longitudinal perspective, ideally developed with the consumer in a collaborative manner, and helps to make sense of evolving information through the consumer journey via the development of hypotheses that can then guide care planning. It may include, but is not limited to, information regarding risk. It was also recognized that there are a range of formulation approaches available, including both theoretical and atheoretical approaches, and that current use of broader formulations across the service was inconsistent. How prevention-oriented risk formulation related to the broader formulation approaches was not clear.

A working group was engaged by GCMHSS in early 2019 to develop a formulation which addressed these issues. The working group included representatives from Child and Youth, Adult, Older Persons, and Alcohol and Other Drugs services within GCMHSS, as well as lived experience advocates, educators (including those with a statewide role), and Pisani, author of [34].

The working group created the “Integrated Formulation,” a prevention-oriented risk formulation suitable for gathering data about and guiding clinical responses to risks of violence, vulnerability, and suicide. The Integrated Formulation was shaped to do the following:

- Build on a familiarity with the “5 Ps,” with the specific aim of integrating this structure with a number of other important aspects of formulation. The “5 Ps” is an atheoretical formulation approach which synthesizes information under the headings of Presenting, Precipitating, Predisposing, Perpetuating, and Protective.
- Move from a focus on problems and deficits to integrating a more strengths-based approach and a more holistic view of the consumer, contributing thereby to the creation of more individualized care plans.
- Promote a more collaborative process in the development of the formulation and explicitly integrate the goals of the consumer into the formulation.
- Include a “pause to reflect” (cognitive forcing function) on the data gathered (more enduring and more dynamic factors) during risk screening and documented in the Risk Screen form. In addition to the central consideration of more enduring and more dynamic factors, consideration should also be given to the meaning of the events for the consumer. For example, in the case of suicide, some theoretical frameworks consider feelings of humiliation, social defeat, entrapment, thwarted belongingness, or burdensomeness to be particularly significant [30, 47], while for violence the senses of losing status, feeling provoked, or feeling humiliated are important.

- Embed an overt consideration of diagnosis, with a prompt for a “pause to reflect” to specifically challenge cognitive bias. This prompts consideration of a range of differential diagnoses (Mental Illness, Substance Use, Personality Disorder, Physical Illness, and Cognitive Impairment).
- Integrate a prevention-oriented risk formulation into the broader formulation, bringing together risk for suicide, violence, and vulnerability into a single formulation.
- Provide a practical approach to give staff clearer guidance on integrating the prevention-oriented risk formulation.
- Focus strongly on how the formulation links into an individualized care plan.

Later in 2019, a second statewide working group trialed a number of approaches to formulation across the state and obtained feedback from clinical teams. The Integrated Formulation obtained positive feedback, with the caveat that it would require training to accompany its rollout. There was variability across different services with respect to their familiarity with prevention-oriented risk formulation, so training specific to the use of this approach was also a requirement for some services.

A range of resources was developed with a focus on supporting implementation within teams and developing commitment to the approach. These included consumer and clinician handouts to support the collaborative development of formulation and sharing; handouts and posters of the flowchart of the Integrated Formulation, including prompts for considering the details to include in each section; a fictional consumer scenario which gave tangible examples of the Integrated Formulation; and webinars which gave insights from the perspective of Alcohol and Other Drugs and Child and Youth services, as well as raising cultural considerations. A video was produced to present the perspectives of consumers, carers, and clinicians regarding the benefits of the Integrated Formulation, with particular reference to collaborative approaches. Later, a further statewide video resource was produced, modeling the use of the Integrated Formulation as an effective and comprehensive, yet efficient, communication tool within a busy Emergency Department setting.

Further work is being carried out to continue to support clinicians as they implement the Integrated Formulation into an increasing number of teams. This is being implemented through a Brief Breakthrough Collaborative methodology, [2] supporting clinicians across the state to embed formulation, with one of the options being the Integrated Formulation. The project is being supported by the Queensland Mental Health Alcohol and Other Drugs Branch. A range of tools for evaluation are being developed, including audits, feedback surveys, and word searches within the electronic medical record.

What Comes Next

Prevention-oriented risk formulation has gained traction in many areas since 2016 and is becoming a highly prominent model in the suicide prevention community. It is now on the cusp of even wider adoption in Australia and the USA, with the approach

being rolled out across New South Wales in Australia, at a national level with the Australian Department of Veteran Affairs, and in several state-level projects in the USA. In light of this widespread adoption, preparatory steps are being taken for the next stage of development and scholarship.

The first step is to carefully consider the lessons that have been learned in large public health systems, such as Gold Coast Mental Health and Specialist Services. The challenges these systems have faced, and the solutions they have developed, provide a playbook for preparing other systems for change. In particular, the data gathered so far points toward the importance of informing and engaging leadership across the system to gain widespread support for a paradigm shift. In addition, strong educational support at all levels is a *sine qua non* for success, including ongoing training, mandatory training when onboarding new staff, and continuous data-driven quality improvement. With educational processes and materials now in their 5th generation, and empirical data to help inform us about what works [33], we now know what it takes to transfer learning into practice and to support sustained fidelity. The good news is that this training can be delivered rapidly and without imposing a heavy burden on already busy staff, so long as it is implemented thoughtfully [45].

The next phase of development and implementation will involve adapting the processes that have been tested in large organizations to make them appropriate for smaller systems and institutions (community-managed systems, NGOs, etc.). It seems likely that these smaller organizations will have significant advantages that can be leveraged, in that they may have more agility concerning workflows, procedures, and documentation, which are more challenging to change in very large systems.

With fidelity measures and systems for organizing change now in place in some systems, more research is needed to understand the precise effects of a prevention-oriented approach to risk on patient care and outcomes. A particular challenge to research on risk formulation is that it is often implemented as part of the adoption of a wider Zero Suicide framework that includes changing other elements of care at the same time. Consequently, it can be difficult to isolate the effects of the formulation from the other changes that usually accompany it, such as improved care planning, enhanced support pathways, integration of lived experience perspectives, and changing workforce attitudes. Nevertheless, research is ongoing.

One study in New Zealand (Fortune et al. unpublished) is carrying out a qualitative examination of service user and clinical staff experiences of prevention-oriented risk formulation to gather data about the effect of using the formulation on those involved. A second study (Veich et al.) is using a dynamic weight list design and a randomized rollout to evaluate the effectiveness of the SafeSide Framework for Recovery-Oriented Suicide Prevention, a suicide prevention framework that has prevention-oriented risk formulation at its heart.

It is also expected that ongoing research at GCMHSS will continue to yield important insights. In particular, the rollout of the Integrated Formulation will provide valuable data on the time savings generated by a combined risk formulation approach, while study of care plans will provide a vital link between assessment, treatment, and planning.

to provide a comprehensive presentation of the NCM and establish its contribution to the conceptualization and the assessment of imminent suicide risk. The first section of the chapter provides a comprehensive review of the underlying reasons for the creation of this model and the ways in which its components address common pitfalls in clinical conceptualizations of and assessment of imminent risk for suicide. The second section presents the different components of the model and the empirical evidence that supports each component as well as the model as a whole. The third and the last section of this chapter proposes a comparison of the NCM and the other leading models of suicide in the extant literature.

Introduction

The narrative crisis model of suicide (NCM) is a dynamic multistage model of suicide which incorporates well-documented long- and short-term risk factors for suicide. Very innovative and yet in continuous dialogue with the other models of suicide in the extant literature, the NCM emerged out of the urgent need to better understand, assess, and treat imminent risk for suicide. This *raison d'être* will be presented in the first section of this chapter, followed by a description of the model's components and their empirical support in the second section. Last, we will compare the NCM to other models of suicide in order to highlight their shared features as well as the NCM's unique contribution to risk assessment and prevention.

The NCM's *Raison D'être*

Research suggests that about 50–70% of individuals who died by suicide saw a mental health professional or a healthcare provider within 1 month before the suicide [19, 48], raising concerns over the effectiveness of current methods to assess and treat imminent risk for suicide. Recent findings suggest that most suicide attempters deny experiencing suicidal ideation when asked about it by healthcare providers [47] and that only 25% of those who died by suicide between 1996 and 2016 ever disclosed suicidal intent [18]. While the phenomenon of patients hiding their suicidal ideation from their clinicians has been increasingly documented in the literature [5, 6, 36, 44], such denial can also be accurate since ideation and intent fluctuate [31, 41] and may emerge moments before actual suicidal behaviors [24, 73]. Altogether, these findings highlight the absolute necessity to develop clinically relevant models to guide clinicians' assessment of imminent risk without relying on patients'

self-disclosure. This gave the first major impetus to develop the narrative crisis model of suicide.

The second reason can be traced to the growing body of research suggesting that while traditional risk factors for suicide discussed in the literature (i.e., mood disorders, past suicidal ideation and attempts, and predisposition traits) predict suicidal behaviors across the lifetime, they do not detect individuals who are at imminent risk [17, 25, 26, 56, 57, 69, 76], prompting researchers to investigate acute psychological processes indicative of imminent risk [2, 6, 26, 71]. Pioneers in this effort, Hendin et al. [34] suggested that feelings of desperation, hopelessness, abandonment, self-hatred, rage, anxiety, and loneliness may reflect the presence of a “suicide crisis” (p. 363) indicative of an acute risk. The suicide crisis syndrome (SCS), originally named *suicide trigger state* [88], was further developed to identify individuals at risk for engaging in suicidal behaviors in the short term. The SCS is characterized by a pervasive sense of frantic hopelessness, which can be described as entrapment with a sense of urgency and desperation, accompanied by affective disturbance, loss of cognitive control, hyperarousal, and social withdrawal [9, 15, 72]. As will be discussed in the next sections of this chapter, the SCS is significantly predictive of short-term suicidal ideation and behaviors [10, 91] and can thus serve both as a diagnostic tool, capable of guiding clinicians’ judgment of their patients’ imminent suicidal risk, and a conceptual formulation of the psychological processes that trigger suicidal ideation and behaviors.

Incorporating the contribution of long-term and short-term risk factors into a more comprehensive framework was nevertheless needed to help clinicians understand one’s progression towards suicidal behavior and suicide. A comprehensive framework was also necessary to inform suicide risk assessments, in which chronic factors could be evaluated together with acute factors to conceptualize and determine patients’ long- and short-term risk. Additionally, a comprehensive model was important to design effective treatments specifically targeting each stage in the cascade of processes that subserve the transformation of long-term risk factors into acute risk for suicidal behaviors. This was the third and last impetus for the development of the narrative crisis model of suicide, a model that provides a comprehensive empirically supported and clinically relevant framework to understand, assess, and treat suicidality [27].

The Narrative Crisis Model of Suicide: A Dynamic Diathesis-Stress Multistage Model

The NCM posits that when individuals experience negative stressful life events, those with long-term risk factors may develop certain views of themselves and society as a whole referred to as the suicide narrative. During the development of this narrative, individuals cling onto unrealistic life goals and perceive themselves to be defeated, humiliated, burdensome, and incapable of belonging. This eventually culminates into a perception of no future [21, 27]. As a corollary to the suicide narrative, individuals may develop the suicide crisis syndrome, an acute pre-suicidal

state of affective and cognitive dysregulation indicative of imminent risk for suicidal ideation and behaviors [28].

Long-Term Risk Factors

Also referred to as distal risk factors or trait vulnerabilities, certain interpersonal, social, psychological, or historical characteristics were shown to increase the likelihood of suicidal ideation and behaviors across the lifetime [20, 37, 76]. Among the childhood history and personality trait factors, a history of child abuse [40], insecure attachment [66], perfectionism [35], and impulsivity and deficits in problem solving [81] were demonstrated to be related to long-term suicidal risk. Additionally a history of parental mental illness and antisocial personality disorder [30] and mood disorders in the family were also found to increase one's long-term risk for suicide [49, 58]. Lastly, one's history of previous suicide attempts and recurrent depressive episodes was also found to increase long-term risk [65]. While such factors do not predict short-term suicide risk [17, 25, 26, 56, 58, 69, 76], their inclusion in the NCM enables clinicians to make more precise assessments about their patients' propensity to move up the stages of the model in the event of a stressor.

Stressful Life Events

Based on the diathesis-stress approach underlying the NCM, stressful life events (also referred to as stressors) are powerful catalysts able to activate pre-existing long-term risk factors and trigger imminent risk for suicide. Overall, the literature supports

the strong relationship between recent stressful life events and increased suicidal risk. Recent stressors have indeed been shown to be a precursor for proximal suicidal ideation and behaviors, particularly economic/financial strains and interpersonal problems [13, 54, 63]. A recent study suggested that some stressors such as interpersonal trauma may contribute to suicidal outcomes more than others [1]. This contrasts with prior work which suggested that the timing, rather than the type of stressor, may contribute to suicidal outcomes [70]. In their most recent study on the NCM, Cohen et al. [22] suggested that stressful life events serve as a mediator in the relationship between trait vulnerabilities and concurrent or near-term suicidal thoughts and behaviors.

The Suicidal Narrative

The suicidal narrative is a cognitive state triggered by the interaction between stressful life events and long-term risk factors, which precedes near-term suicidal behaviors [21]. This concept originally derived from research regarding life narratives suggests that identity is an ongoing and narrative process where individuals incorporate their life experiences into an internalized and evolving self-story [52]. The suicidal narrative is one such self-story, where an individual's response to stressful life events involves the internalization of distorted self-representation which leads to emotional distress and an increased risk for suicide [21].

The suicidal narrative includes seven components, or themes, that were established as short-term psychological risk factors for suicidal behavior in the empirical literature. The first, thwarted belongingness, occurs when an important need for connection or belonging is unmet [78]. This need to belong is described by Baumeister and Leary [5] as a fundamental desire to form stable, positive, and lasting interpersonal attachments. Thwarted belongingness comprises loneliness, or the experience of disconnect between self and others, and the absence of reciprocal care, where a person feels as though they have no one to care for or, in turn, care for them [78]. Associations between loneliness and suicide ideation (e.g., [74]) and social isolation and suicide (e.g., [75]) were documented in the literature.

The second theme is perceived burdensomeness which emerges from an unmet need for social competence [79], that is, when an individual feels incapable of having meaningful social interactions or relationships. Two indicators of perceived burdensomeness are self-hatred and a person's belief that they are a liability, namely, that others may believe that their death is worth more than their life [78]. Prior research found a relationship between self-hatred and suicidal behavior (e.g., [33, 67]). Research has also associated suicidality with expendability in different populations, for instance, in cancer patients [80] and adolescents [74]. Additionally, the perception that one is a liability or a burden may be related to major suicide risk factors, such as homelessness, incarceration, unemployment, and severe physical illnesses [78].

Per the interpersonal theory of suicide [39], the simultaneous, stable, and unchanging presence of both thwarted belongingness and perceived burdensomeness is a proximal cause of active suicidal desire [78]. Empirical studies indeed found the

concurrent experience of both factors to be associated with suicide ideation [14, 64, 77].

The third and fourth components of the suicidal narrative are defeat and fear of humiliation. The integrated motivational-volitional model of suicidal behavior emphasizes the role of both factors, in addition to entrapment, as proximal predictors of suicide ideation [60]. Defeat is also a crucial component of the cry of pain model of suicide (CoP; [83]) and is related to its concept of arrested flight, or the belief that one is socially trapped, coupled with a strong desire for escape [29]. Per Klein [42], humiliation occurs when one feels disparaged, scorned, or ridiculed for what one is rather than what one has done. The notion that suicide is a response to the fear or threat of humiliation is suggested in the literature [32, 42].

The fifth and sixth themes of the suicidal narrative involve a failure to disengage from unattainable goals and a difficulty redirecting one's efforts toward more realistic ones, respectively. These concepts were derived from the conceptual formulations and empirical findings on goal disengagement theory, which suggested that the ability to disengage from unrealistic goals and to reengage with more achievable ones is crucial for one's well-being and physical health [53, 85–87]. Being caught in an action crisis, in which one struggles to let go of unachievable goals and develop more adaptive ones, was found to trigger elevated distress [16]. O'Connor et al. [61] found that the inability to reengage with new goals was predictive of suicide ideation. Last, difficulty with goal reengagement was shown to predict future self-harm behavior in a population of suicide attempters [63].

The six themes of the suicide narrative are understood to trigger one's perception of having no future. Conceptualized as the cognitive counterpart of entrapment, the perception of no future involves one's belief that their challenges will never abate nor improve.

The Suicide Crisis Syndrome

The suicide crisis syndrome (SCS) refers to an acute pre-suicidal state of affective and cognitive dysregulation that represents the last step of the narrative crisis model (NCM) and is its core feature [27]. Coined the suicide trigger state, the original formulation of the SCS was conceptualized as a panic-like syndrome that combined symptoms of frantic hopelessness (a desperate sense of entrapment), ruminative flooding (negative, uncontrollable thoughts), and near-psychotic physical symptoms (pain) [88]. This formulation was grounded in the work of Hendin et al. [34] who coined the term suicide crisis to describe a state suggestive of short-term suicide risk consisting of desperation, hopelessness, abandonment, self-hatred, rage, anxiety, and loneliness. Models of suicide such as Baumeister's [4], which emphasizes the connection between hopelessness and suicide, provided further inspiration for the suicide trigger state. Additionally, research on the relationship between psychosis and suicidal attempts [68], combined with empirical findings on ruminative thoughts

by Nock and Kazdin [55], and their somatic correlates provided support for the inclusion of a ruminative flooding and near-psychotic somatization, characterized by physical pain that derives as a direct consequence of a panic-like state, in the condition.

The suicide trigger state [88] was revised and renamed the suicide crisis syndrome (SCS) after the inclusion of additional short-term risk symptoms for suicidal behavior documented in subsequent research [27, 89]. The resulting five SCS dimensions were (1) frantic hopelessness or entrapment, characterized by feeling trapped in an unbearable situation from which one could not escape despite a desperate urge to do so; (2) panic/dissociation, characterized by an altered sensorium and derealization, both associated with panic; (3) ruminative flooding characterized by uncontrolled and racing thoughts and somatic symptoms such as headache and pressure in the head; (4) emotional pain characterized by feelings of mental pain and anguish; and (5) fear of dying characterized by conscious fears of sudden death. This version of the SCS was found predictive of short-term suicidal attempts [3, 28, 90].

The current formulation of the SCS reflects the most recent empirical evidence on near-term risk factors for suicide and forms the basis of a diagnosis that was proposed to the DSM-5 scientific review committee. The SCS is characterized by a pervasive feeling of frantic hopelessness/entrapment (Criterion A) accompanied by affective disturbance, loss of cognitive control, hyperarousal, and social withdrawal (Criterion B) [9, 15, 72, 91]. In a state of entrapment, one experiences their current life situation as unbearable and perceives the escape from it as both urgent and unbearable. Entrapment was found to be significantly predictive of imminent suicidal behavior [38, 45] and was highlighted as the symptom with the highest number of interconnections to the other SCS symptom, suggesting its central role in triggering or reinforcing the SCS symptoms [9].

Affective disturbance can be presented through four discrete symptoms either individually or simultaneously [72]: (1) emotional pain, or *psychache*, is characterized by intense feelings of torment and hurt; (2) rapid surge of negative emotions and feelings toward the self and others; (3) extreme anxiety, manifested by a severe sense of panic and dread, potentially accompanied by somatic symptoms including headaches or panic attacks; and (3) acute anhedonia, experienced as the loss of interest and pleasure in activities that were previously enjoyed.

Loss of cognitive control involves several psychological progressions that may present in one or various combinations of four symptoms [72]: (1) ruminations about one's problem; (2) cognitive rigidity presented as an individual's incapacity to consider different outcomes or coping approaches; (3) ruminative flooding, which involves physical pain such as headaches or head pressure resulting from the overwhelming ruminations; and (4) failed thought suppression, characterized by multiple, unproductive attempts to suppress upsetting or disturbing thoughts.

Hyperarousal involves several distressing emotional and somatic experiences reflected in four symptoms that could be present independently or simultaneously [72]: (1) agitation; (2) hypervigilance, displayed by an acute and

disproportionate sensitivity to sensory stimuli and conceivable dangers present in the environment; (3) irritability; and (4) insomnia, involving trouble falling asleep or staying asleep for the duration of the night.

The last symptom of Criterion A in the SCS, social withdrawal, is reflected avoidance of social interactions with one's environment, in addition to their perceived lack of belongingness to their social surroundings [72].

The current formulation of the SCS, about to be proposed to the DSM-5 scientific review committee, was found predictive of near-term suicidal behaviors among an inpatient population [91]. Those meeting full criteria for the SCS were more likely to have a post-discharge suicide attempt as compared to those meeting partial criteria. Neither current suicidal ideation nor depressive severity was significantly related to post-discharge attempt within this sample. Analyses were replicated on an adult outpatient sample [92]. More recently, the SCS was found to significantly predict suicidal attempts as well as suicidal behaviors in a mixed sample including both inpatients and outpatients [12].

Empirical Validation of the NCM

In addition to the empirical validation of its components, a growing body of research provides emergent empirical support for NCM as a model. First, a study by Cohen et al. [20] suggested that the relationship between a group of trait vulnerabilities (perfectionism, impulsivity, substance abuse, insecure attachment, poor social support, and childhood trauma) and lifetime suicidal ideation and behaviors was significantly mediated by the suicide crisis syndrome (original version). In another study, Cohen et al. [21] demonstrated that the suicide crisis syndrome (original version) mediates the relationship between several themes of the suicidal narrative (i.e., thwarted belongingness, perceived burdensomeness, fear of humiliation, and social defeat) and lifetime suicidal ideation and behaviors. More recently, Bloch-Elkouby et al. [11] investigated the relationship between four out of five components of the narrative crisis model assessed longitudinally and explored the model's ability to predict prospective suicidal ideation and attempts. The study's findings suggested that each step of the model significantly predicted the next and that the model accounted for 10.8% of the variance in prospective suicidal ideation as well as 40.7% of the variance in prospective suicidal attempts. Last, a serial moderation and mediation analysis by Cohen et al. [22] investigated the model's predictive validity and the relationship between its stage components. This study, too, supported the hypothesized relationships between the model's components with the exception that stressful life events were found to mediate (but not to moderate) the relationship between trait vulnerabilities and the suicidal narrative. The study also demonstrated that the SCS (original version) predicted concurrent and prospective suicidal ideation and behaviors.

Contrasting the NCM with Other Models of Suicide

Stress-Diathesis Models

The NCM shares common features with several models of suicide. First and foremost, it is not the only model that includes a stress-diathesis approach, according to which distal factors act as a predisposition to respond to stress with suicidal ideation and behaviors. To cite just a few such models, Linehan's biosocial model of borderline personality disorder, for example, posits that innate emotional vulnerability, when coupled with an invalidating environment, can decrease one's ability to regulate their emotions, cognitions, and behaviors [23, 46]. The resulting trait-like dysregulation is then exacerbated in the face of stressors such as rejection, eliciting maladaptive coping strategies involving suicidal and non-suicidal self-harming behaviors [46]. While both models highlight the contribution of trait vulnerabilities and dysregulation in one's risk for suicide, they also differ in several ways. First, the trait vulnerabilities included in the NCM encompass a wider gamut of traits and childhood events. Second, while the NCM does not reject the idea that certain individuals' dysregulation puts them at chronic risk for suicide, it strives to underscore the very chain of processes through which such risk materializes. In this chain, the role of life stressors is central, for it triggers existing trait vulnerabilities, leading to the emergence of a suicidal narrative, followed by a state of affective and cognitive dysregulation described by the suicide crisis syndrome, which in turn predicts suicidal outcomes.

According to Beck's cognitive diathesis-stress model [81], dispositional vulnerability factors involving trait hopelessness and the propensity for attentional fixation predispose individuals to respond to stress by engaging in quickly escalating suicidal crises characterized by state hopelessness, anxiety, and agitation [81, 82]. The NCM's emphasis on entrapment, loss of cognitive control, and agitation as key components of the SCS parallels Beck's model.

Meanwhile, Mann's stress-diathesis model of suicide [50, 49] proposes that low serotonin and norepinephrine levels associated with impulsivity and hopelessness represent a diathesis for suicidal behavior. In the experience of a psychosocial crisis or psychiatric illness, these biological vulnerabilities, when present in an individual, may lead to suicidal behavior. Similarly to Mann's model vulnerability stage, the NCM includes a long-term risk factor stage that may be activated by stressors. The NCM departs from this model, though it includes two intermediate stages (the suicide narrative and the SCS) that play a pivotal role in the emergence of suicidal ideation and behaviors as well as a disinguisable suicide-specific mental state of the SCS.

Ideation-to-Action Models

In recent decades, the growing body of research showing that most suicide ideators do not engage in suicidal behaviors [59] has led to increasing interest in ideation-to-action models of suicide, which differentiate risk factors for suicide ideation from

risk factors for suicidal behavior [59]. While the NCM fundamentally differs from these models, as discussed below, it also presents important similarities. For example, according to the interpersonal theory of suicide (IPTS; [39]), active suicidal ideation results from an experience of perceived burdensomeness and thwarted belongingness. Both factors were included in the NCM as components of the suicidal narrative. Per the IPTS, suicidal ideation can morph into suicidal behaviors when an individual has an acquired capability for suicide [78], which may stem from past experiences such as prior suicide attempts or childhood maltreatment [78]. This later component is one of the trait vulnerabilities included in the NCM.

A second ideation-to-action theory of suicide is the integrated motivational-volitional model (IMV; [62]). The model describes a wide array of factors that may trigger the motivational stage, through which suicidal ideation arises, and the volitional phase, in which suicidal intent may trigger behaviors. Although three such factors are shared with the NCM, defeat, humiliation, and entrapment, their contribution to the emergence of suicidal behaviors is conceptualized quite differently.

The three-step theory (3ST) is a more recently proposed ideation-to-action theory of suicide and comprises three steps [43]. The first step suggests that a combination of pain (generally, psychological pain) and hopelessness can develop into passive suicide ideation. In the following step, suicidal thoughts may escalate into active suicide ideation if a person's experience of pain overwhelms their feelings of connectedness. Ideation may progress into action in the final stage, in the presence of dispositional (e.g., low fear of death), acquired (e.g., exposure to combat), or practical (e.g., access to lethal means) capability for suicide. While the 3ST posits that pain contributes to the development of suicidal thoughts, in the NCM pain belongs to the affective dysregulation symptom of the SCS, and it relates to imminent suicidal behavior. The NCM also includes entrapment/frantic hopelessness, which is close but not identical to hopelessness in the 3ST. Similar to pain, entrapment plays a central role in the development of suicidal behavior rather than ideation in the NCM. Connectedness, as described in the 3ST, refers to one's attachment to anything (e.g., a project, role, or hobby) or anyone that gives them a sense of purpose and supports their desire to live [43]. Disrupted feelings of connectedness to people, or perceived burdensomeness and thwarted belongingness in the NCM, play an important role in both theories in the emergence of suicide ideation.

The main difference between the NCM and the ideation-to-action models presented above lays in their conceptual formulation of suicidal ideation and its contribution to suicidal behaviors. The underlying assumption of ideation-to-action models is that suicidal behaviors emerge as the result of one's progression from suicidal thoughts of increasing severity to actual plans and actions [51]. The NCM diverts from this assumption, and rather posits that several paths can lead an individual to make a suicidal gesture. As mentioned above, the main path described by the NCM involves the progression from trait vulnerabilities to the suicide crisis syndrome via the suicide narrative, in such a way that conscious suicidal ideation and behaviors may both emerge within a short timeframe (as documented in the literature, see [24, 73]), as a result of the acute and severe affective and cognitive dysregulation caused by the suicide crisis syndrome. Accordingly, conscious suicidal ideation may not appear until the very last

moment or even not at all. This formulation fits in well with recent research showing that suicidal ideation fluctuates over time [31, 41] and thus does not build up in a linear way. Notwithstanding, the NCM does not preclude the possibility that in some cases, the culminating perception of no future triggered by the suicide narrative and its resulting SCS may elicit intense suicidal ideation that matures into planning and premeditated suicidal behaviors. With regard to such cases, and more generally in light of the growing literature documenting that patients tend to hide their ideation from their clinicians [7, 8, 36, 44], the absence of suicidal ideation in the NCM may be all the more critical, for it provides a comprehensive array of tools to assess and long-term and imminent suicide risk regardless of patients' readiness to disclose their suicidal ideation and intent.

Another key difference between the NCM and other theories of suicide is that the former postulates the existence of an acute distinct suicide-specific mental state, the SCS, which can be described and diagnosed regardless of patients' experience of suicidal ideation. In a recent review paper, Calati et al. [15] highlighted several biomarkers susceptible to being involved in the etiology of the SCS, paving the path for future pharmacological studies targeting the proposed biomarkers. Furthermore, several ongoing studies currently investigate the impact of pharmacological treatments on the SCS and their ability to reduce near-term suicidal risk.

Conclusion

The NCM provides a clear and yet comprehensive conceptual framework, which incorporates the long- and short-term risk factors for suicide documented in the empirical literature on suicide. Namely, each component in the model has been shown to predict suicidal ideation and behaviors. Furthermore, the model as a whole was also found to be predictive of suicidal ideation and behaviors in cross-sectional [22] and prospective [11] studies. While innovative, the NCM synthesizes features common to several models of suicide and can be expected to evolve further in order to reflect the new findings that continue to shed light on the processes that lead to suicidal ideation and behaviors. The contribution of the NCM to suicide risk assessment, prevention, and treatment can be thought of as multilayered. First, it provides clinicians with an empirically supported conceptual formulation of the progression from long-term risk factors to suicidal outcomes, upon which specific cases conceptualizations can be developed to enhance clinicians' ability to understand their patients. Second, the comprehensive inclusion of long- and short-term risk factors in the NCM can guide clinicians' assessment of their patients' imminent as well as future suicidal risk as well as future. Third, the clarity and conciseness of the model allow clinicians to use it as a psychoeducational tool that can help patients develop insight into the different processes that trigger suicidal ideation and behaviors. Fourth, the SCS can be taught in medical schools within a medical framework, similar to other DSM syndromes. Last but not least, the NCM provides the first framework for a comprehensive and multilevel approach to suicide prevention which includes psychotherapy, psychopharmacology, stress management, and means restriction.

Abstract

The emotional responses of clinicians to patients at risk of suicide have long been discussed in the theoretical psychodynamic literature but have been largely neglected by empirical research. A substantial body of evidence supports the notion that clinicians often experience strong negative or positive emotional reactions to suicidal patients (Gurrister and Kane, *Community Ment Health J* 14(1):3–13, 1978; Maltsberger and Buie, *Arch Gen Psychiatry* 30(5):625–633, 1974; Modestin, *Br J Med Psychol* 60:379–385, 1987; Richards, *Br J Guid Couns* 28:325–337, 2000). Nascent yet compelling research has yielded data to suggest

that a unique combination of both positive and negative emotional responses may be characteristic of clinicians' responses to these high-risk patients (Galynker, *The suicidal crisis: clinical guide to the assessment of imminent suicide risk*. Oxford University Press, Oxford, 2017; Soulié et al., *Arch Suicide Res* 24(1):96–118, 2018; Yaseen [71, 72]). This phenomenon could prove to be a valuable addition to current suicide risk assessment models and may have notable implications for diagnosis of suicide risk in clinical settings.

Clinician emotional response · Suicide

In recent years, suicide has risen to become the 10th overall leading cause of death in the United States, accounting for 48,344 deaths in 2018 alone [17]. Among Americans aged 10 to 34, suicide is the second leading cause of death [17]. The rate of suicide in the United States has continued to rise at an alarming rate, increasing 33% from 1999 to 2017 [36]. This rate has continued to accelerate steeply in recent years increasing 1% between 2000 and 2006, 2% from 2006 to 2016, and 4.9% in 2017 [17]. In addition to death by suicide, it is estimated that 9.8 million Americans consider suicide annually, and 1.3 million citizens make a suicide attempt each year [1]. Not only is suicide a growing concern in the United States, it also represents a major cause of preventable mortality throughout the world.

Estimates of global suicide deaths reached 817,000 in 2016 [51]. The number of global suicide attempts are even higher, reaching an estimated 25 million each year [23]. Due to the massive amount of stigma associated with suicide, these estimates are conservative, and in reality, these rates may be even higher than reported. The staggering rates of suicide in the United States and across the world have prompted countless efforts by researchers to identify risk factors associated with suicidality, investigate the efficacy of treatments, and work towards accurate prediction of suicide [30]. This research has undoubtedly deepened our understanding about the nature of suicidal thoughts and behaviors and has informed the development of many models and theories on the subject. In spite of these efforts, suicide rates have shown no appreciable decline in recent years.

Effect on Clinicians

In light of the growing suicide epidemic, prevention efforts have increased among mental health professionals. Although the majority of individuals who die by suicide have no contact with mental health professionals before their death, data suggests that one third of suicidal patients come into contact with a mental health professional in the month immediately prior to their death [58]. The far too common nature of suicide is also reflected in the experience of therapists, psychiatrists, counselors, and other mental health professionals. The majority of mental health clinicians, estimates

range from 50% to 95%, have worked with patients expressing suicidal ideation or a history of suicidal behaviors [61]. Surveys indicate that as many as half of all psychiatrists will lose a patient to suicide in their career [18]. Though interaction with suicidal individuals is commonplace, these interactions can be taxing for many clinicians. In fact, working with suicidal patients has been found to top the list of work stressors for therapists, and suicide death of a patient is recognized as an occupational hazard for mental health professionals [2, 19, 26].

The loss of a patient by suicide has a profoundly disturbing and potentially career-ending impact on clinicians [2, 21, 37]. Where other healthcare professionals experience the death of a patient as an unfortunate, yet sometimes inevitable, consequence of an illness, mental healthcare providers often experience the suicide death of a patient as a personal therapeutic failure [33, 47]. Following the suicide death of a patient, many clinicians are flooded with responses like grief, shame, guilt, fear of blame, and self-doubt [37]. Not only does the death of a patient by suicide have the potential to elicit powerful emotional reactions, it is also clear that the high-stakes task of working with suicidal individuals can also elicit strong emotional reactions on the part of the clinician. The potential for clinical judgment to be influenced by the taxing nature of work with suicidal individuals, combined with the lack of reliable suicide risk assessment tools, makes both assessment of suicide risk and treatment of suicidality a monumental undertaking for experienced and inexperienced clinicians alike. The proportion of suicidal patients who do, in fact, receive mental healthcare prior to completing suicide represents a sizable missed opportunity for targeted intervention and suicide prevention. To this end, suicide risk assessment scales have been developed, but currently none have demonstrated strong positive predictive value [30]. In this light, clinician judgment remains one of the most relied upon tools for establishing suicide risk among patients.

Suicide Risk Assessment Models

The scale and severity of the current global suicide epidemic have inspired a wealth of research aimed at uncovering a set of both proximal and distal risk factors that lead to suicidal thoughts and behaviors. Various researchers have developed their own, often overlapping sets of risk factors, theories, and models aimed at classifying patients into low- and high-risk groups. Recent meta-analyses, however, have pointed out that most suicide risk assessment models have poor predictive ability and limited clinical utility [9, 30]. In fact, despite the nearly 50 years of research on the subject, none of the current models assessed in these systematic reviews performed above chance levels [30]. Furthermore, many risk factors that have been studied extensively are distal, or so-called “trait” predictors. These predictors have limited value in clinical settings. Proximal or “state” predictors are far more useful to mental health professionals assessing imminent suicide risk in patients in clinical settings. The lack of reliable and comprehensive suicide risk assessment models has left practitioners largely unable to distinguish patients who will go on to make suicide attempts from those who will not. Thus far, none of the established

theories on the subject have integrated clinical judgment or the subjective experience of clinicians as an important facet of establishing suicide risk in patients. In this light, quantifying the emotional experience of clinicians in contact with suicidal individuals has potential to enhance suicide risk assessment models and strategies.

Countertransference

Clinicians rely upon their clinical judgment greatly when making treatment decisions. These judgments are comprised of both rational factors such as information gathered from clinical history and emotional factors informed by the clinician's emotional responses to the patient [4]. As posited by Hayes, Gelso, and Hummel [35], the concept of clinician emotional response, referred to as countertransference in the psychodynamic literature, has evolved greatly since it was coined by Freud at the turn of the twentieth century. In fact, the term has now been adopted by some cognitive-behavioral clinicians and researchers who argue that the term has now become transtheoretical [16, 43, 54]. Freud used the term to describe the psychoanalyst's unconscious and conflict-basted reaction to the patient's transference. In this original view, countertransference was viewed as a problematic phenomenon that should be minimized or eliminated completely [35]. This classical view on the role of countertransference persisted until the 1950s, when a totalistic conception of the phenomenon emerged [44].

According to the totalistic perspective, all of the therapist's reactions to the patient fall under the umbrella of the term countertransference, and every reaction is thought of as an important tool for understanding the patient [35]. A third conceptualization of the phenomenon emerged when it was posited that the clinician's reactions to the patient should be viewed as a complement to the relating style of the patient. In this view, the reactions elicited in the therapist by the patient should not be permitted to play out in therapy but can provide insight into the patient's interpersonal and relational style. The final conception of countertransference, the relational view, regards the phenomenon as originating mutually from the unresolved conflicts, needs, and behaviors of both the client and the therapist [35, 49].

Though the term has been conceptualized in a variety of specific ways, each with their own set of limitations, the definition has since evolved both in literature and in everyday dialogue to generally describe any emotional reaction that a therapist has in response to his or her client [32, 35]. By and large, the classical, totalistic, complementary, and relational definitions are used interchangeably and without much nuance. Few empirical studies on the subject specify which definition of the term is to be used and most simply utilize a loose definition of the term and operationalize countertransference phenomena using scales such as the Therapist Response Questionnaire (TRQ) which assess a wide array of emotional, cognitive, and behavioral reactions to the patient [73]. It is true, however, that the prevailing current view on

countertransference has moved away from the classical perspective and now emphasizes the potential of clinicians' reactions to help them gain a deeper understanding of the patient. In fact, a substantial body of research has identified distinctive patterns of clinician response to various patient characteristics including depression and various forms of personality pathology [10, 22, 63]. For the purposes of this review, the terms countertransference and clinician emotional response will be used interchangeably to refer to the emotional reaction experienced by clinicians in response to interacting with a patient at risk of suicide.

Negative Countertransference Phenomena

Though limited empirical research has been conducted on countertransference phenomena as it relates to work with suicidal patients, evidence suggests that overall, clinicians tend to have negative emotional responses or countertransference when working with suicidal patients. These negative responses, initially conceptualized as "countertransference hate" by Maltsberger and Buie [45], are thought to arise out of a combination of aversion and malice towards the patient. These emotional impulses have the potential to result in either the formation of a malicious, anti-therapeutic relationship between therapist and client or can alternatively result in the total abandonment of the patient. Although the latter may appear to be the less threatening option, abandonment of the suicidal patient is likely to precipitate the suicidal crisis [45]. The experience of "countertransference hate" is undoubtedly an uncomfortable experience for therapists, many of whose professional identities rest upon a foundation of non-judgment and compassion for the patients they serve. This discomfort with the aversion and malice felt towards the suicidal patient can prompt clinicians to turn this hate inwards. In this scenario, when confronted with feelings of malice towards the patient, the clinician redirects these negative emotions towards the self ("It is not the patient that I hate, it is myself. I lack the competence and ability to help my patient"), resulting in feelings of inadequacy, helplessness, and hopelessness [45].

Additional negative emotional responses to the suicidal patient typically include anxiety, irritation, and avoidance [11]. Though these patients cannot be accurately categorized in the same group as patients at risk of suicide, per se, qualitative studies of countertransference with regard to patients requesting physician-assisted suicide revealed similar patterns of negative emotional response in clinicians [67]. When confronted with their patient's wish for death, physicians exhibited anxious, overwhelmed, and helpless responses. These negative reactions also appear to emerge as the suicide risk of the patient escalates. A study of psychiatric residents working in the emergency department of a general hospital found that residents expressed anger and anxiety towards patients at high risk of suicide but expressed warmth towards individuals at low risk [27]. Clinician's negative emotional responses to patients expressing suicidal ideation have more recently been found to include specific reactions such as lack of hope, confusion, distress, and sense that the patient's life had little worth [48].

Positive Countertransference Phenomena

Though clinicians tend to have overwhelmingly negative reactions to patients at risk of suicide, working with these patients also has the power to elicit positive countertransference reactions in some clinicians [71]. These reactions include concern, protectiveness, and the desire to nurture the patient [34, 50, 55]. In work with patients at risk for suicide, some clinicians report feeling hopeful for treatment [71]. In their description of “countertransference hate,” Maltzberger and Buie [45] also theorized that as a defense against the hatred felt towards the suicidal patient, the therapist may turn this hatred into its opposite. In this circumstance, the clinician may indulge in fantasies of rescuing the patient and have a great deal of anxiety relating to their desire to cure or help the patient [45]. Though this type of positive response to patients at risk of suicide is useful in maintaining therapeutic affiliation and positive regard for the patient, overindulgence in concern for patients can result in overinvolvement or inappropriate optimism [45]. Thus, positive countertransference also has the potential to become counterproductive and may even result in crossing of therapeutic boundaries [55].

Mixed Countertransference Phenomena

The bulk of research on the subject has identified negative emotional reactions on the part of clinicians who interact with suicidal patients; however, evidence for both negative and positive countertransference phenomena has been identified in the present literature. These findings appear to be at odds, but this paradox could reveal a key pattern in the way that clinicians respond to suicidal individuals. It has been recently suggested that a combination of opposing emotional responses could be a specific feature of countertransference with patients at risk for suicide [62, 72].

In research on the Suicide Crisis Syndrome, a pre-suicide mental state, and its proposed DSM-V criteria, Galynker [31] identified two varieties of CT that may characterize the experience of interacting with patients at risk of suicide. The first, coined anxious overinvolvement, is characterized by “the presence of unrealistic expectations and efforts to save the patient from their painful situation” (p. 204) alongside anxiety and hope for the patient. It can be understood that anxious overinvolvement captures the key elements of the positive countertransference phenomena identified in the extant literature. The second is referred to as rejection-avoidance and features anger, hostility, and hopelessness which lead to “contact avoidance and premature termination of treatment” (p. 208). This dimension can be interpreted to represent the negative clinician emotional responses previously identified by researchers. Galynker [31] theorizes that both of these specific varieties of countertransference result from lack of awareness or maladaptive regulation of emotional responses on the part of the clinician. This theory was investigated further in research by Yaseen et al. [71] that examined the relationship between clinician emotional response and patient suicidal behaviors. In this study, conflicting clinician emotional responses of distress and hopefulness were predictive of suicidal behavior

post-discharge. Additionally, a combination of opposing clinician emotional responses was significantly associated with identifying patients who attempted suicide versus those who had not [71]. When treating imminently suicidal patients, clinicians reported moderately positive feelings including hopefulness for treatment alongside negative feelings such as avoidance, distress, and feeling overwhelmed by the patient [71]. Furthermore, factor analysis of psychiatry residents' responses to the Therapist Response Questionnaire Short Form provided additional evidence to support this idea [72]. The conflicting emotional response pattern of distress combined with hopefulness was significantly associated with suicide outcomes of patients post-discharge. Notably, this interaction effect retained significance when controlling for patient factors such as entrapment, depression, and suicidal ideation [72].

Research by Soulie and collaborators [62] on clinician emotional response to suicidal patients yielded further evidence in support of this mixed countertransference phenomenon. Factor analysis revealed a seven-factor structure that depicts the varieties of countertransference experienced by clinicians in their interactions with patients at risk of suicide. The two most salient of these factors experienced by clinicians in the sample were "entrapped/rejecting" followed by "fulfilled/engaging" reactions. The first factor is characterized by apprehension, desires to reject the patient, feelings of inadequacy, and hopelessness, whereas the second depicts eagerness to engage with the patient and professional fulfillment. The emotional states described by these two factors clearly mirror the varieties of countertransference described by Galynker [31]. These two opposing experiences together accounted for 70% of variance of the emotional experiences of clinicians in the sample. This data provides additional support for the theory that a paradoxical combination of negative and positive countertransference is characteristic of clinicians' emotional reactions to individuals in suicidal crises.

It is also compelling to consider the ways in which the emotional response of clinicians appears to mirror aspects of the suicidal state experienced by patients [62]. When interacting with patients at risk of suicide, clinicians themselves seem to experience similar feelings of inadequacy, hopelessness, and entrapment. Soulie and colleagues [62] hypothesize that this specific pattern of mixed countertransference can be understood as an adaptive, and possibly necessary, coping stance. In this view, the negative aspects of this countertransference pattern represent clinicians' empathic engagement with the suicidal state experienced by their patient, and the positive countertransference represents an attempt by the clinician to sustain hope and therapeutic engagement in spite of the patient's suicide risk [62]. According to this perspective, both positive and negative emotional responses serve important functions in the therapeutic relationship.

Individual Differences Among Clinicians

It is clear that specific patterns in clinicians' responses to suicidal patients have emerged in recent studies, but these interactions may also be influenced by individual factors. One such individual factor that has long been thought to contribute to

countertransference is attachment style of the clinician [41]. Studies have shown that healthcare professionals with a secure attachment style demonstrate higher self-reported levels of empathy towards patients than insecurely attached clinicians [25, 42]. It may be extrapolated from this data that securely attached clinicians may experience more positive countertransference than their insecurely attached colleagues. Theoretical orientation of the clinician also appears to be related to specific countertransference with patients at risk for suicide. Research indicates that psychodynamically oriented clinicians have significantly higher rates of “entrapped/rejecting” reactions to suicidal patients, whereas clinicians with an eclectic theoretical orientation demonstrate more “aroused/reacting,” “informal/boundary crossing,” and “mistreated/controlling” responses [62]. Clinicians with an eclectic theoretical orientation also exhibited less “protective/overinvolvement” countertransference than psychodynamic or cognitive-behavioral clinicians. Although it is indeed a possibility that theoretical orientation impacts the emotional responses experienced by clinicians, an alternative explanation provided for these differences is that theoretical orientation may simply have an impact on the countertransference literacy of the clinician [62]. In other words, clinicians with training in certain schools of psychological thought may have significantly increased or decreased awareness of their negative emotional responses towards patients.

Effect of Countertransference on Outcomes in Therapy

Though empirical research on the specific patterns of countertransference to suicidal individuals is still in its nascent stages, literature on the subject definitively indicates that work with suicidal individuals often elicits intense emotional reactions in clinicians [45, 55, 71]. Developing a greater understanding of clinicians’ emotional responses is crucial because unrecognized or unmanaged negative countertransference in response to high-risk patients has the capacity to damage therapeutic alliance, can impair clinical judgment, and may even contribute to poor patient outcomes.

Countertransference and Therapeutic Alliance

Therapeutic alliance, also referred to as the helping alliance or working alliance, is a fundamental element of psychotherapy that plays a pivotal role in treatment. In short, therapeutic alliance refers to the quality of the relationship between client and therapist and is comprised of three components. These include therapist-patient bond, agreement on the goals of therapy, and agreement on therapy tasks [14]. Therapeutic alliance has been demonstrated to be a strong predictor of outcomes across diagnoses and theoretical orientations [29]. Though it is important in all treatment, establishing a strong and genuine therapeutic alliance is especially critical in the treatment of suicidal individuals [8, 28, 39, 40].

The characteristics that typify many patients at risk for suicide also constitute challenges to establishing a productive working alliance [46, 59, 60]. The negative interpersonal perceptions and hopelessness characteristic of many individuals experiencing suicidal ideation are likely to result in reduced trust in the clinician and increased negative expectations of therapy [3]; Beck et al. [7, 65]. Similarly, clinicians' negative emotional responses to these patients also constitute a barrier to the therapeutic alliance. Distress, anxiety, unease, and aversion towards the patient may unwittingly result in rejection of the patient, decreased empathic communication, and increased mistrust between client and clinician [38].

It is clear that unmanaged emotional responses to suicidal patients is not conducive to formation of strong alliance between client and therapist and in some cases is liable to promote the formation of a poor or maladaptive therapeutic alliance. Quality of therapeutic alliance has a direct and undeniable impact on therapeutic outcomes. Data from qualitative surveys of clinicians indicate that countertransference with suicidal patients often "shifted the boundaries of the therapeutic alliance" and ultimately damaged therapy outcomes [55]. Though negative emotional responses to suicidal patients are common at the outset of therapy, they do not necessarily have an irreparable effect on alliance. The development of countertransference literacy can help repair ruptures in the therapeutic relationship [57]. Furthermore, effective management of negative countertransference and the eventual formation of a good working alliance has the potential to mitigate or reduce suicidal ideation in a number of cases [53].

A substantial body of research supports the notion that the emotional response of clinicians has a direct impact on treatment outcome [15, 41]. Evidence suggests that countertransference reactions are inversely related to therapy outcomes and that successful management of countertransference reactions is significantly related to better outcomes in therapy [35]. The stakes are undoubtedly significantly higher when this idea is applied to work with suicidal patients. It has been suggested that unmanaged countertransference reactions may even contribute to patient suicide [50]. Conversely, successful management of emotional reactions in therapy on the part of mental health professionals has been shown to result in faster decreases in suicidal ideation among patients [53]. A retrospective study conducted by Hendin et al. [37] found that clinician anxiety preceding the suicide death of a patient resulted in coercive or ineffective actions and insufficient treatment of symptoms. This notion is even more alarming when coupled with data suggesting that clinicians may often be totally unaware of their own emotional responses to patients and, thus, may be unable to appropriately identify or regulate them [66].

Awareness and Training

It is clear that, in general, clinicians appear to lack attunement to their emotional reactions to patients and that this appears to have great potential for negative outcomes specifically among patients at risk of suicide. New strategies for managing countertransference are needed, as meta-analytic studies have highlighted that the countertransference management factors studied to date do not, in fact, play a significant role

in attenuating these reactions in clinicians [35]. Evidence suggests that increased awareness of emotional responses to patients is directly associated with decreased countertransference behaviors in clinicians [56]. Thus, researchers have begun to consider the possibility of training mental health professionals in emotional self-awareness in order to remedy this issue. One strategy has been proposed by Cureton and Clemens [24], which makes use of affective constellations, a component of Interpersonal Process Model [64]. According to this strategy, clinicians should engage in self-reflection with particular attention to the affective constellations (i.e., sadness-anger-guilt, anger-sadness-shame, etc.), felt in reaction to the suicidal patient [24].

In practice, clinicians should attend to their own emotions throughout and following a session and should also have the opportunity in supervision to engage in honest discussion about the negative emotional reactions they may have experienced. If employed, this strategy not only may benefit the clinician in increasing their awareness of countertransference phenomena but also can aid the clinician in empathizing with the patient by drawing attention to the similarities that often exist in the emotions felt by both the patient and the therapist [24]. This may be critical as empathy has been shown to aid in the management of negative countertransference behaviors [35].

Diagnostic Value of Countertransference

Empirical research on the emotional reactions of clinicians to patients at risk of suicide is still in its nascent stages, but a growing body of evidence has emerged in support of the diagnostic value of clinician emotional response in other domains. Patterns of clinicians' subjective experience during initial patient evaluation have been associated with psychiatric diagnoses such as schizophrenia, cluster B personality pathology, and major depression [52]. Studies have identified unique patterns of clinician response to patients with a variety of diagnoses. For example, responses that include feelings of being abused, manipulated, or annoyance have been associated with narcissistic personality disorder patients [10], while overwhelmed and disorganized responses have been associated with borderline personality disorder (Colli et al. [20]). This body of literature underscores the importance of clinicians' subjective experience in the diagnostic process. The mixed countertransference phenomenon identified by Yaseen et al. [71, 72], which has been replicated by Soulie and collaborators [62], has already demonstrated value in prospectively identifying patients at high risk of suicide. This compelling preliminary research that has identified a distinct profile of clinicians' responses to suicidal patients could comprise a powerful novel tool for suicide risk assessment.

Clinical Implications

Although unregulated negative countertransference reactions have potential to damage therapeutic outcomes, once clinicians have gained insight into their emotional responses, it is possible to consider the immense potential this has as a clinically

useful tool. Clinical judgment, comprised of both rational and emotional factors, has been shown to be a powerful predictor of short-term suicidal behavior [4, 68]. This is a noteworthy finding as clinical judgment informed by emotional response is a tool that does not rely on patient self-report of suicidal ideation. Honest disclosure of suicidal ideation is difficult for many individuals, and concealment or denial of suicidal thoughts and behaviors is quite common among patients in psychotherapy [13]. Fear of hospitalization or shame may lead individuals contemplating suicide to conceal these ideations from their clinician. In an anonymous survey of patients in long-term psychotherapy, 31% of individuals reported having lied to their therapist about suicidal thoughts [12]. Capitalizing on the powerful signals provided by clinicians' emotional responses to patients could be a valuable resource for identifying patients at risk of imminent suicide, even if ideation is never discussed or disclosed. These emotional signals could also be used to identify patients at highest risk of attempt among patients who do, in fact, disclose their suicidal thoughts to a clinician. In this way, even negative emotional responses have potential clinical value if clinicians remain conscious of these reactions.

Future Directions

Countertransference and its potential utility to clinicians has long been discussed in the theoretical psychodynamic literature, yet empirical research on this subject has been neglected, especially with regard to patients at risk of suicide. Clinicians' emotional responses to patients at risk of suicide should be integrated into suicide risk assessment models. Preliminary studies have had promising results, but more empirical studies on the specific patterns of countertransference with suicidal patients are warranted to explore this phenomenon. Additionally, research on the mechanisms that underlie these patterns of countertransference should be conducted in a variety of treatment settings and with clinicians of varying theoretical orientations. More research on the diagnostic potential of unique patterns of clinician emotional reactions to discriminate between high- and low-risk patients should also be carried out.

Conclusion

Many clinicians can attest to experiencing a powerful emotional reaction or an undeniable "gut feeling" in response to interacting with a patient at risk of imminent suicide. Budding research on this topic has begun to identify a unique set of countertransference reactions that have potential clinical utility in suicide risk assessment. Preliminary data indicates that the countertransference reactions of clinicians specific to suicidal patients is prospectively associated with patients' suicidal thoughts and behaviors [72]. More specifically, a combination of both highly distressed and hopeful countertransference was linked to these suicide outcomes [72]. This data suggests that mixed clinician emotional response has potential

as a diagnostic tool for identifying high suicide risk among patients. Furthermore, researchers have begun considering the ways in which clinicians can develop better countertransference literacy and increase their attunement to the emotional responses brought on by these patients. Although empirical research on the subject is still in its earliest stages, evidence regarding the patterns of clinicians' emotional responses to patients at risk of suicide has shown great promise in becoming a powerful source of information for clinicians engaged in suicide risk assessment.

Abstract

Communicated suicide ideation is typically seen as the gateway to further evaluation of the patient as possibly suicidal. Both our research scales and our methods of clinical enquiry about SI remain lost in the weeds of unaddressed questions about just what it is we want our patients and our research subjects to tell us when we ask “the ask,” and just what is the meaning of what they tell us when they respond affirmatively to our questions about it. In this chapter the question of how we ask about suicide is addressed in both research and clinical settings and focused from the perspective of the language used in and the time frames incorporated into the questions posed. Best practice recommendations regarding how and when to ask “the ask” are offered to maximize the elicitation of a patient’s suicide ideation and its character. Cautions are also offered to help understand the clinician’s hesitancy to ask about suicide ideation, the meaning of

Suicide ideation · Risk assessment · Death by suicide

Introduction

The primary tool used by mental health clinicians to gain an understanding of a patient is the psychiatric interview. The term "psychiatric interview" is used here generically to refer to an interview conducted by mental health clinicians, not just psychiatrists, to ascertain and characterize a patient's presenting problems. Although the psychiatric interview may be preceded by self-report data gathered by scales administered in the waiting room or during emergency department triage and assessment, it is in the interview itself that the patient is afforded an opportunity to have their presenting mental health problems evaluated and treatment planned for. The psychiatric interview is also the primary vehicle used by the clinician to drive the assessment of the patient's risk for suicide.

The clinical interviewer must assume *a priori* that any and all patients have the potential to be suicidal, even when their chief complaint does not involve mental health concerns and/or when they only present with low-acuity chief complaints. In a classic study of "occult suicidality," of 1590 patients seeking emergency department care for nonpsychiatric reasons, more than 11% acknowledged passive suicidal ideation and more than 8% admitted to active suicide ideation; and nearly all of these patients also reported symptoms consistent with mood, anxiety, and/or substance-related disorders commonly observed among suicidal patients [1]. Further, it is important to be reminded that there are a great many medical conditions that are associated with heightened risk for suicide, ranging from those that are life-threatening and debilitating to those that are transient and treatable [2], hence the clinician should also consider that patients presenting with certain medical complaints might have potential to be suicidal.

The process of conducting a suicide risk assessment (SRA) is one of data collection. Inherent in this process and crucial to gaining an understanding of a potentially suicidal patient, no less that patient's potential risk to engage in suicidal behavior, is a clinician's recognition that the identification of a patient as at risk of suicide is not simply dependent on that patient communicating suicidal thoughts either spontaneously or in response to clinical enquiry.

As stated by Silverman and Berman [3 p421],

"An SRA gathers data about observable and reported symptoms, behaviors, and historical factors presented by a patient that are associated with suicide risk and protection, ascertained by way of psychiatric interview; collateral information from family, friends, and medical records; and/or screening tools,"

Hence, an SRA should begin with first gathering information about the individual regarding the presence of risk factors associated with heightened suicide risk, followed by gathering information related to a patient's suicide ideation [4].

A Focus on Suicide Ideation

Communicated suicide ideation (SI) is typically seen as the gateway to further evaluation of the patient as possibly suicidal. Tragically, a patient's denial to a posed question regarding the presence of suicidal thoughts is too often interpreted as an absence of any significant suicide risk and no further enquiry ensues. Multiple studies have found that the majority of patients who die by suicide deny that they are thinking of suicide when last asked by a clinical practitioner before, and often within days of, their death [5–18]. The mean proportion of patients in these studies that denied having SI at the last evaluative session before their death by suicide was 62%.

Just as a patient's admission to having SI does not automatically equate to that patient having near-term suicide risk, a patient's denial of SI should not be construed to mean that the patient is not suicidal; nor does it mean that they do not have SI. There are myriad reasons why patients on the brink of taking their life will not disclose their suicidal thoughts to clinicians [3, 19]. Among these are the following:

- Shame: "I believe that suicide is an admission to others that I am weak."
- Stigma: "I will be seen as crazy; it is a taboo to discuss suicide."
- Hopelessness: "I believe that nobody can help and that I am incapable of being helped."
- Fear of:
 - Negative Judgment: "I will be ridiculed and judged negatively by others."
 - Retribution: "I will lose my job and my career in the military/police/as a pilot. ..."
 - Involuntary Hospitalization: "The police will come to my door and forcibly remove me."
- Control/Autonomy: "I do not want to be thwarted should I decide to kill myself;" "Once I deny having suicidal thoughts, I will be discharged from this psychiatric ward."
- Religiosity: "I believe that suicide is a sin, hence my thoughts are sinful."
- Subconsciousness: "I have not had any thoughts of suicide" (but, in truth, I am simply not aware of these and they may well burst into consciousness at any moment).
- Temporality: "My thoughts wax and wane; at this very moment I am being asked, I am not thinking of suicide."

This last reason has been clearly demonstrated in a study by Kleiman and colleagues [20] who collected smartphone-based ecological momentary assessments (EMA) of SI and its severity every 4 to 8 h over a 28-day period from patients, both those who had made past year suicide attempts and/or those who had been

hospitalized for SI. For nearly all participants SI varied dramatically over the course of most days with nearly one third of all ratings of SI being a standard deviation above or below the previous response from its earlier rating. It is important for clinician's to keep in mind that SI is at times fleeting and context specific.

The context-specificity of SI means that an individual's life circumstances, no less psychology and biology, fluctuates. The common situational triggers for suicide typically involve loss – real, threatened, or anticipated – of something highly valued by the individual. For young adults, for example, it is an intimate partner problem that most often characterizes the precipitating circumstances of a death by suicide; for younger individuals, it is a conflict with parents. For others, it may involve a threat to one's finances, as in unemployment; a pending legal action, or something else that threatens a loss of autonomy or face. Suicides rarely occur in the absence of some triggering event that represents the proverbial straw that breaks, in this case, the individual's psychological back. For this reason Litman [21] coined the term “suicide zone” to characterize the period of heightened suicide risk that suicide-vulnerable individuals move in and out of, at times briefly and at times for long periods, as their life circumstances fluctuate. As Shea [4 p49] reminds us, “it is always wise to maintain a healthy respect for how rapidly [patients] can move in and out of a suicidal frame of mind.”

Nevertheless, the clinical enquiry must involve questions about suicidal thoughts. It is with this in mind that we now can address the intent of this chapter: How to ask about suicide?

How to Ask About Suicide

First, the good news. More than a dozen papers, published between 2001 and 2017, have unanimously found that asking patients and/or research subjects about SI has no iatrogenic effect, such as leading to an increase in SI [22, 23]. Obversely, Dazzi et al. [22] found that acknowledging and talking about suicide, in fact, might reduce rather than increase SI, a finding consistent with qualitative studies of pediatric and adult medical inpatients who remained supportive of suicide risk screening after they themselves had been screened [24, 25].

As Berman and Silverman [26] have written elsewhere, what is not such good news is that our field is confused about how to ask “the ask,” no less about what it is we are asking. Both our research scales and our methods of clinical enquiry about SI remain lost in the weeds of unaddressed questions about just what it is we want our patients and our research subjects to tell us when we ask, and just what is the meaning of what they tell us when they respond affirmatively to our questions about it. Shea [4 p120] shares a wonderful vignette to illustrate this point. When asked by a trainee “Have you had any thoughts of wanting to hurt yourself?” the patient responded, “no.” Given that this patient had a large number of suicide risk factors, the trainee later asked, “Have you had any thoughts of wanting to kill yourself?” to which she responded, “Oh yes, I’ve thought about it a lot.”

As another illustration, upon enquiry a patient denied that they were thinking about suicide, and later after discussion regarding how they were coping added, “but I feel suicidal.” This distinction is important, as Jobes [27] has noted, suicidal feelings may “include a sense of impulsivity, an urgent need to do something self-destructive, or a sense in the patient that he or she deserves to be punished in a self-destructive manner” (p. 102).

Words matter and it is the clinician’s responsibility as a standard of care to peel off the layers upon layers of a patient’s communications to truly understand what they are thinking, feeling, and telling us.

How Is Suicide Ideation Addressed in Research Scales?

In the United States, the Joint Commission [28] released a Sentinel Event Alert (24 February 2016) that offered recommendations for a broad range of healthcare organizations (emergency, primary care, and behavioral healthcare settings) in identifying and responding to individuals at risk for suicide. Included in these recommendations was one to “screen all patients for suicide ideation, using a brief, standardized, evidence-based screening tool.”

Perhaps the most commonly used screening tool is the Patient Health Questionnaire (PHQ-9), a 9-item self-report scale widely used as an initial screener for depression. Item 9 on the PHQ-9 asks, “Over the last 2 weeks how often have you been bothered by the following problem: thoughts that you would be better off dead, or of hurting yourself in some way?” Item 9, by itself, often has been used as a measure to assess the prevalence of suicidal ideation in research studies and as a brief screening measure to assess suicide risk in primary care waiting rooms [29].

Both Thompson, Henkel, & Coyne [30] and Silverman and Berman [3] have commented on the PHQ-9, item 9, asserting that it addresses SI via a compound question that is vague in its phrasing and inclusive of multiple types of thoughts referencing both passive and active SI and/or non-suicidal self-injury in the very same question. Just how is the clinician to understand a patient’s affirmative response? Are they responding to an understanding of the question as addressing non-suicidal self-injury (NSSI) or of attempting suicide? Moreover, the phrasing “bothered by” suggests being worried by having SI, or feeling guilty for having SI. Many patients with SI do not have these emotional responses to their SI, no less some employ thoughts of suicide as a way of coping with painful emotional states, hence would have no such reactions to their SI and would appropriately answer “not at all” to this question.

Similar problems pertinent to the use of research scales addressing SI have been noted elsewhere. For example, Valtonen, Suominen, Sokero, Mantere, Arvilommi, Leppämäki, et al. [31] asked 191 bipolar patients whether they had ever seriously considered suicide during their current bipolar episode and further evaluated SI via the Scale for Suicide Ideation (SSI), the Beck Depression Inventory (BDI, Item 9) and the Hamilton Depression Scale (HAM-D, Item 3). In all, three-quarters (74%) of patients had SI as measured by at least one of the three measures; but less than

one-third (29%) met the criteria for having SI on all three measures. These researchers concluded that, “Who is classified as having suicide ideation depends strongly on the definition and means of measurement of suicide ideation” [31 p53].

In another study by these Finnish researchers [32] the prevalence of SI was assessed in six different ways among primary care patients diagnosed with major depressive disorder (MDD). These researchers found that the prevalence of SI among these patients was strongly influenced by the method of its assessment. Of 153 MDD patients seen in primary care, only 8% tested positive for SI across all six measures.

Two scales more currently in vogue address this problem head on by posing to the patient multiple questions about the presence of SI, beginning with questions more broadly addressing thoughts construed as passive SI, then moving to questions more specific to active SI. The ASQ [33] is a four question yes-no instrument; two of these questions address suicide ideation within specific, but vaguely defined time frames:

1. In the past few weeks, have you wished you were dead?
2. In the past few weeks, have you felt that you or your family would be better off if you were dead?
3. In the past week, have you been having thoughts about killing yourself?

The Columbia Suicide Severity Rating Scale (C-SSRS) [34] similarly begins with questions asking about thoughts or wishes to be dead or not alive anymore or wishes to fall asleep and not wake up (i.e. passive SI) and proceeds to questions about more active thoughts such as “Have you had any thoughts about killing yourself?” (i.e., active SI).

Indeed, screening scale items ask “the ask” in very different ways, and therefore affirmative responses have to be considered within the narrow frames of each specific scale question. To that extent, if these scales were to be used in clinical practice, guidelines such as those published by the American Psychiatric Association [35] (and the United Kingdom’s National Institute for Health and Clinical Care Excellence [36] make clear that they should not be used in lieu of a direct patient interview, but, rather, only as an adjunct to help inform and structure the clinical evaluation of suicide risk. The practitioner that relies solely on a screening scale is avoiding a face-to-face encounter with a potentially suicidal patient and the deep follow-up evaluation that is essential to effective treatment planning and intervention.

How Is Suicide Ideation Addressed in Clinical Enquiry?

In truth, we know little about how questions about SI are asked by clinicians, no less how often providers asked questions about SI at healthcare appointments, notably those held in proximity to the death by suicide of a patient. Three studies offer some data of interest to this last question, two of which are specific to evaluations of

patients who died by suicide; the third, and the only one of this sort to be published to date, is a fly-on-the-wall picture of real-time practitioner behavior.

Bommersbach, Chock, Geske, & Bostwick [9] reviewed medical records pertaining to the last year of life of 66 individuals who died by suicide in Olmstead County, Minnesota, noting whether the provider (not further identified by profession) documented asking about suicide. They found that an enquiry about SI occurred in only 27 (41%) of these cases. Berman [7] similarly reported on charted observations within the last 30 days of life of 157 suicide decedents from 40 US states and the District of Columbia who were in clinical care (by caregivers from multiple professions) and found that no enquiry was made about the presence of SI at the very last evaluation of 25 patients (16%). One-half (49%) of these last visits occurred within 2 days of these patients' deaths and almost three-fourths occurred within 7 days.

On a more general level, looking at psychiatric outpatients, McCabe, Sterno, Priebe, Barnes, & Byng [37] audiovisually recorded 319 psychiatrist-patient appointments in outpatient psychiatric clinics in urban, semirural, and rural areas in the UK. Of these 319 opportunities to ask about the presence of SI, SI was assessed on only 83 occasions (26%) by 35 psychiatrists.

Case Example A 21-year-old, single white female is hospitalized for the ninth time in the last 5 years due to poor outpatient management of her diagnosed anorexia nervosa and major depressive disorder. She has a history of NSSI, panic attacks, sleep disorder, and both prior SI and suicide attempt by overdose. On the day of this last admission she stated, "If I had a gun, I would shoot myself." On the unit she is charted as progressing well and after 5 days is removed from suicide watch. After a distressing visit from her father in which he behaved inappropriately, she was noted to have purged her lunch. Although observed to feel both "desperate" and "tense" that afternoon, no questions about SI or suicidal feelings were asked by the psychiatric resident on duty. That evening she jumped out of her hospital bedroom's fifth floor window.

Why Are Clinicians Hesitant to Ask About Suicide Ideation?

Cole-King and Lepping [38] note that professionals in the UK may feel disinclined to ask "the ask" because they lack confidence in knowing how to ask and how to respond. Quinnett (2019) opines that clinician discomfort with suicidal patients and fear drives this sort of avoidant behavior. Further, he posits, based on some earlier work [39] that this fear derives from perceived insufficient training. A more recent study [40] confirms this in finding that when providers feel sufficiently trained and efficacious in their work with suicidal patients, there may be a reduction in emotional and behavioral impediments to asking about SI.

McCabe et al.'s [37] study using real-time data examined how UK psychiatrists initiated enquiries about suicide risk (when they did, as the majority did not – see above) and found that the overwhelming majority (75%) of questions asked were

phrased in the negative, as in, “You don’t have thoughts of harming yourself?” Not surprisingly, when the question was negatively framed, patients were significantly more likely to say they were not suicidal than when the question was positively framed.

A second UK study [41] looked at how mental health practitioners addressed self-harm risk in young people in actual practice and found that of those practitioners who addressed the question (the majority did not), the two most common approaches were (a) incremental – a building-up style beginning with questions about emotions such as how the patient behaviorally dealt with frustration or sadness, then moving into specific questions about the link between emotion and self-harm; and (b) normalizing and externalizing – relying on being required by an external authority to ask the question, as in, “There is a question we have to ask everybody. . . have you ever thought about. . .?” Quinnett [42] opines that this polite probe (“. . . we have to ask everybody. . .”) “is a pre-apology for a pending face-threat question.”

Issues to Consider in Deciding How to Ask “the Ask”

1. Should We Ask About Thoughts of Suicide or of Self-Harm?

In the United States, the question asked typically focuses on thoughts of suicide or killing oneself. In the UK and elsewhere across the globe, the preferred term is self-harm. Of course, we do not know whether our patients understand that these are meant to be synonymous, especially if they interpret a question about self-harm to refer to what otherwise would be labeled as non-suicidal self-injury (NSSI). No study has yet been published that helps us to understand the connotations of these terms in our patients’ minds, to determine the meaning of their responses if either in the affirmative or negative. To confound this, NSSI and suicide attempts frequently co-occur [43–45].

As noted earlier, item 9 of the PHQ-9 asks both about active SI or NSSI (“hurting oneself”) and passive SI (“being better off dead”), and clinicians, as well, have no consistent guidance as to which question best affirms a patient’s suicidal thoughts that are most associated with near-term potential to engage a suicidal behavior. We know that suicidal thoughts are dynamic and can change rapidly; but just how rapidly passive thoughts of suicide may shift to active thoughts, planning, and/or impulsive action has simply not been established by research nor sufficiently explored to date.

2. Should We Ask About Both Active and Passive Thoughts of Suicide (or Both)?

In one sense, this is a difference that may make no difference. Active SI has little to no greater predictive value with regard to future suicidal behavior compared with passive SI [3]. Moreover, given the aforementioned EMA study by Kleiman et al. [20], it is highly probable that passive SI may shift to both active SI and a decision to

act on suicidal thoughts in a matter of minutes to hours. Berman [7] offers data to this point in finding that of 43 patients in or recently in clinical care who responded positively to having SI when last asked shortly before their deaths by suicide, almost equal proportions affirmed having active versus passive SI. Findings such as these bring into question the underpinnings of scales such as the C-SSRS that establishes a Likert scale for assessing SI with active ideation having greater clinical and predictive import than passive ideation. Notably, the positive predictive value of the PHQ-9 against the C-SSRS has been found to be only 22.5%, providing evidence that these two measures are essentially measuring different constructs [46].

Case Example A 44-year-old, married white male university professor in outpatient psychiatric care was found hanging in the basement of his home. He had a history of MDD and Generalized Anxiety Disorder. In addition he was observed to have angry irritability, feelings of hopelessness, sleep problems, and a family history of suicide. He was being seen in outpatient cognitive behavior therapy by a psychiatrist for the past 3 weeks. At his last outpatient session, 2 days before his death, he shared thoughts “of ending it all,” but no further elucidation of his suicide ideation or assessment of his risk of suicide was made.

3. What Is the Best Time Frame in Which to Ask “the Ask”?

Empirical study has yet to sufficiently address the time period in which to frame the questions clinicians (or screening scales) should ask about SI. Which of the following options has the greatest predictive value: “Are you currently thinking...?”; “In the past 2 weeks have you been thinking...?”; “In the past few weeks or month have you had thoughts...?”; “Have you recently been having thoughts...?”; “Have you ever had thoughts...?” The best answer to date is that none of these time frames may be best! Beck, Brown, Steer, Dahlsgaard, and Grisham [47] found that a retrospective report of SI *at the worst point in a patient’s life* was a better predictor of eventual death by suicide than was current (or presumably recent) SI. These findings have been replicated by Joiner, Steer, Brown, Beck, Pettit, and Rudd, [48].

4. Does Any if This Even Matter?

Large and Ryan [49] characterized as “mythical” clinicians’ belief that the presence of SI is a crucial sign for estimating the likelihood of a patient’s future suicide. In fact, as described by Silverman and Berman [3], the reporting of current or recent SI has very little correlation with the development or expression of suicidal intent or the progression from SI to suicide attempt or to death by suicide in the near term. A study by Britton, Ilgen, Rudd, and Conner [50] illustrates this last point. These researchers found that only 11% of 301 patients who died by suicide within 7 days of contact with Veterans Health Administration healthcare providers reported having SI at that contact and an even smaller percentage (7.5%) reported SI to their healthcare provider within the last 30 days of life.

Nevertheless, SI is associated with both suicide attempt and death by suicide in the long term. Hubers, Moaddine, Peersmann, Stijnen, VanDuijn, Vander Mast et al. [51] recently conducted a systematic review and meta-analysis of 81 studies to assess whether the expression of SI predicted subsequent death by suicide in various populations, including nonpsychiatric and psychiatric populations. They found that the absolute suicide risks were highest in psychiatric populations, with a suicide risk during the first year of follow-up of 1.4% compared with 0.23% in nonpsychiatric populations. Fortunately, the overwhelming majority of patients expressing SI do not die by suicide. Nevertheless, the assessment of SI is a priority in people with psychiatric disorders, if for no other reasons than the relatively strong association SI has to psychiatric disorders and other suicide risk factors, and because SI is a signal for treatment intervention [52].

How to Ask “the Ask”

Even though the field of Suicidology lacks consensus on how to ask “the ask,” there is general consensus on approaches that might be considered as best practices in maximizing the likelihood the patient will disclose suicidal thoughts, if present.

1. Establishing rapport with the patient and conveying empathy for both their help-seeking and the presenting problems that led to their help-seeking are crucial to maximizing trust and the patient’s comfort and openness to communicating their inner world. Building a solid therapeutic alliance and creating a safe environment are, perhaps, the most important steps in reducing the patient’s resistance to sharing their thoughts and emotions.
2. Expect the patient to be guarded and resistant and be on guard against strong counter-transferential reactions to provocation. Motto and Bostrom [53] found that a negative or mixed reaction to the patient by the interviewer was one of nine high risk variables that were associated with suicide by depressed and suicidal patients within 60 days of a hospital-based evaluation.
3. Patients at risk of suicide more often than not have interpersonal skill deficits. Accordingly, and as suggested by Rudd [54], reinforcing the patient’s openness should be straightforward and simple with empathic statements such as, “I know it’s difficult to talk about such personal issues, particularly with someone you just met. It takes a lot of personal courage to do so.”
4. Understand that at the heart of a suicidal person’s thinking is some level of psychological and emotional pain [55] and reducing that pain may ultimately be the first target of therapeutic intervention. Shneidman [56] conceptualized that pain as “psychache” and, with this in mind, approached his patients with an opening such as, “Where do you hurt?” rather than with the more typical “What brings you in to see me today?”
5. Open the enquiry about the potential presence of suicidal thoughts, if they have not been spontaneously communicated or otherwise indicated on a waiting room screening form, by empathically resonating to what the patient has communicated

and normalizing (Shea, 2012) the patient's pain and possible suicidal thoughts, such as by saying "Sometimes when people have had the kind of experiences you have told me about they have had thoughts that it's just too much to bear, like 'I'm just too tired of it all' or 'I'd just rather be dead or never wake up.' Have you had any thoughts like that?"

6. Always ask the ask reasonably early in the interview as (a) you will need sufficient time to fully explore it, if present, and (b) you will have sufficient opportunity to return to "the ask" later in the interview.
7. Always ask "the ask" in at least two ways and at least two times. One of the "asks" should be very direct and explicit using the words "kill yourself" or "suicide." This latter question should be asked by varying the phrasing of the behavior being questioned ("suicide," "take your life," "killing yourself," etc.). In all cases where the patient denies having any SI, but in which the clinician senses the very real possibility that the patient would be likely to have such thoughts given the emotional pain being described, it is imperative that "the ask" occur a second time after the patient's denial. Phrasing such as, "I know you told me that you have not now or recently been having thoughts of suicide, but given (the patient's reported symptoms and stressors), it would not at all surprise me if thoughts such as these, even fleetingly, crossed your mind. . .".
8. Always explore further and document what kind of thoughts the patient has had by asking "What exactly you have been thinking?" Over and above characterizing a patient's expressed SI as active or passive, always document the patient's SI using the patient's own words.

Text Box Examples of Passive SI in the Patient's Own Words. All of these patients died by suicide within 2 days of making these statements.

- "I would not care if I died"
 - "I don't want to deal with life"
 - "I just want to disappear"
 - "I see no purpose in me going on"
 - "It would be better if I had never been born"
 - "If I died tomorrow, I'd be happy"
 - The only way I can get close to God is to go to heaven."
9. A simple electronic health record (EHR) of SI present or absent, without an accompanying narrative, is insufficient for treatment planning (see Fig. 1).
 10. If the patient denies having current thoughts loop back in time to whether SI was present in recent weeks and, yet again, "at the worst point in your life."
 11. Do not accept at face value secondary minimizations offered by the patient, such as "But, I would never act on those thoughts because (it would destroy my children; I love my family so much; suicide is a mortal sin and I would go to hell. . .)." Berman [57] found that 8 of 43 patients (19%) who died by suicide and

MRN: [REDACTED]	[REDACTED]	[REDACTED]
Visit: [REDACTED]	Gender: Female	
Age: 40y ([REDACTED])		Current Location: Psych02

Suicidality:

☒ Ideation

☐ Intent

☐ means (potentially lethal)

☐ plan

☐ behaviors, including preparatory acts, self-injury, or suicide attempt

Fig. 1 Screenshot of the EHR of a 40-year old-female's inpatient psychiatric evaluation of suicide ideation made after an apparent impulsive suicide attempt by jumping out of a moving car while arguing with her husband

admitted to having SI when last asked before their death, specifically stated that they would not act on their suicidal thoughts because of their concern for how their suicide would hurt their children or family (e.g., “I love my kids too much,” “Only my kids keep me alive,”). If and when the pain is too great to bear and the urge to leave life is overpowering, these seeming deterrents will have no effect. A recently published systematic review of the literature [58] examined this question of whether expressed reasons for living (RFL), such as these, protected against suicidal thoughts and behavior and concluded that RFL (notably moral objections and survival and coping beliefs) may protect against SI and suicide attempt, but the potential protective effect against deaths by suicide is not clear, as no study investigating RFL expressed by individuals who have died by suicide had yet been published.

Case Example A 59-year-old, married white male is admitted to inpatient psychiatric care due to a 6 month worsening depression and anxiety. In the last 3 months he became less functional at work and experienced greatly increased stress; feeling overwhelmed he became fearful he would be fired. His sleep has been severely affected and medications have not been effective. The day before admission, he secluded himself in an empty room for several hours while contemplating hanging himself. In his intake psychiatric interview he described ongoing SI, but “denied any intent to harm himself at this time given his concerns that suicide would invalidate his life insurance policy.” The day after admission, he hanged himself in his hospital room's bathroom.

12. If SI is expressed, engage in an extensive follow-up enquiry, seeking specific details. Consider yourself to be an investigative reporter seeking to understand the what, when, where, and how of current and/or recent thoughts. Seek to clarify the patient's SI, as follows:
 - (a) If passive SI is expressed, explore what might shift the wish to die to the wish to kill oneself: “What do you think would need to happen for you to actively want to take your life?”
 - (b) If active SI is expressed (or if the patient describes the potential for active SI based on the above question). Ask:

- (i) How are you thinking about killing yourself? (or How do you think you would kill yourself?)
- (ii) Do you have access to that method (the gun, a bridge, the pills. . .)?
- (iii) Have you thought out how, when, and where you would do this?
- (iv) Have you rehearsed doing this or prepared for the possibility in some way?
- (v) Have you thought about other ways you might do this?
- (vi) How often do you have these thoughts?
- (vii) When you have them do you seem to dwell on them, have trouble getting them out of your mind?
- (viii) How long do they last (or are they fleeting)?
- (ix) When you have them how intense and/or demanding do they feel?
- (x) Are you ever scared that you won't be able to control these thoughts, that is, that you would act on them?
 - 1. The specific coping skills that individuals utilize when experiencing suicidal urges in order to avert escalation into a suicidal crisis underlie the use of safety plans as a preventive intervention [59]. Examples of suicide-related coping include engaging in distracting activities, seeking social and professional support, and limiting access to lethal means. Individuals who report having a degree of ability to control their suicidal thoughts have been found to be less likely to make a first suicide attempt [60].
- (xi) Is this the first time you have had these thoughts? If not, when did you first have them or similar thoughts? When did you last have them? Have they always been similar or have they been different? Have the circumstances been similar each time?
- (xii) What would most need to happen, do you think, for you not to have thoughts of taking your life?

This line of enquiry is not meant to be an all-inclusive primer for eliciting a patient's SI and its character, but, rather, is designed to lead the clinician to approach the patient's suicidal phenomenology, to best develop an understanding of the patient's mindset in the context of motivating forces leading to the consideration of ending pain via killing oneself. There are myriad ways to ask "the ask" and no agreement as to how best to ask the ask, what time frame best defines "the ask," and/or what terms to use to assert clarity in "the ask."

When to Ask the Ask

There is universal consensus among Suicidologists that asking about the presence of SI is a standard of care question to be addressed at the first evaluative contact with a patient. Just how frequently should "the ask" be asked thereafter is less clear, but the following guidelines appear to be appropriate:

1. Once a patient has initially communicated the presence of SI, follow-up questions should be asked at each and every session, at least until no further SI is admitted to for three consecutive contacts and none of the following conditions exists. The Collaborative Assessment and Management of Suicidality [27] considers this absence of SI for three consecutive sessions one criteria for “suicide resolution,” yet urges continued vigilance for a return of SI.
2. At every outpatient session following inpatient psychiatric hospitalization or emergency department (ED) care for SI or a nonfatal suicide attempt. The weeks to months after hospital-based care for suicidal behaviors are well-documented periods of very high risk [61–63]. Until the psychosocial stressors that triggered the need for inpatient or ED care are resolved and/or the psychiatric symptoms and diagnoses are well-enough controlled, continued vigilance for a return of SI is called for.
 - (a) At any observed change in mental status, environmental stress, or worsening symptoms, notably in this last regard anxiety and agitation and increasing sleep problems. Bjørngaard, Bjerkeset, Romundstad, and Gunnell [64] found that those who had insomnia symptoms had a twofold increased risk for suicide after controlling for depression, anxiety, and substance abuse; and Goldstein, Brent, and Bridge [65] found a ten-fold increased risk for death by suicide in youth who exhibited sleep disturbances in the preceding 7 days. Berman [7] found that 80% and 76% of 157 suicide decedents were observed to display anxiety and/or agitation and sleep disturbances, respectively, within days of their death.
3. For patients with a history of prior suicide attempt, an exploration of the specific triggers for these prior attempt(s) should lead to an understanding of precipitating circumstances that offer an understanding of the patient’s idiosyncratic vulnerabilities and an increase in an index of suspicion for situation-specific times and contexts for the presence of SI.
4. At times of management transition, such as the rotation of psychiatric residents on an inpatient unit, upcoming vacations by the clinical caregiver, etc. Patients in ongoing clinical care are reactive to conditions of instability in their interpersonal world and need to be more closely monitored at these times.

Is the Presence of Suicide Ideation Predictive of Future Suicidal Behavior?

As discussed by Silverman & Berman [3], currently expressed SI is, indeed, a significant risk factor for future suicidal behavior and death by suicide, but is much more closely associated with death by suicide in the long term than it is in the near-term [66, 67]. For example, Simon, Yarbrough, Rossom, Lawrence, Lynch, Waitzfelder, et al. [68] found only a single death by suicide among 1767 psychotic patients (a high risk group) within 90 days of an index outpatient visit in which they responded to item 9 on the PHQ-9 that they were having SI “nearly every day.” In spite of SI having little to no value in predicting near-term death by suicide

and in spite of our recognizing that the communicated presence of SI is neither necessary nor sufficient for the assessment of suicide risk, it remains as an essential component of a standard of care SRA.

Conclusion

Fortunately, only a small proportion of patients with SI die by suicide. Nevertheless, assessment of SI is an essential part of the psychiatric interview. When a patient expresses SI, a full understanding of its motivation and aim and its character and intensity is called for. That understanding is essential to guide the practitioner to develop appropriate treatment disposition and planning to reduce the possibility that thought will lead to lethal action. To date, our knowledge about why and when suicidal thoughts progress to potentially lethal attempts remains rather inadequate [55], but that is not an argument to ignore the potential significance of SI to our understanding of the suicidal individual and his or her future suicidal behavior.

Abstract

The Collaborative Assessment and Management of Suicidality (CAMS) is a flexible and adaptive evidence-based suicide-specific therapeutic framework. At the center of the CAMS approach is the use of the Suicide Status Form (SSF), a multipurpose tool that guides suicidal risk assessment, treatment planning, and tracking of patients who are suicidal. The effectiveness of CAMS (and its use of the SSF) is supported by extensive clinical research through numerous

correlational/open trials, quasi-experimental studies, and five randomized controlled trials (RCTs). CAMS is a suicide-specific intervention, and suicidal ideation and behaviors are therefore kept center stage until suicidality is resolved. A main agenda of the CAMS approach is for the clinician and the patient to collaboratively elucidate and understand key constructs underlying the patient's suicidal state from the patient's point of view. Through the identification and understanding of patient defined "suicidal drivers," the clinical dyad can start the exploration and examination of alternative solutions and adaptive ways of coping that do not require the patient to terminate their life. Thus, CAMS is a patient-centered approach to suicide-specific care that enables the patient to cope differently, ultimately leading the patient to pursuing a life worth living with purpose and meaning.

The Collaborative Assessment and Management of Suicidality (CAMS) Approach

This chapter will describe the Collaborative Assessment and Management of Suicidality (CAMS) approach to working with a range of patients who are suicidal across a variety of clinical settings. Specifically, the chapter will consider the CAMS philosophy and the use of the Suicide Status Form (SSF) to guide clinical care, examine the empirical support for CAMS, and explore next steps for CAMS.

Case Example

"Alice" is 28-year-old white female physical therapist who is referred to a clinical psychologist named "Jen," who has recently transitioned from being a university counseling center staff member into full-time private practice. Alice is distraught over the breakup with her fiancé Bill after a 5-year relationship. In their intake session, Alice acknowledged that she was in crisis after the collapse of her engagement complaining that, "...Bill was my last shot at happiness, and I totally blew it!" Alice stated that the breakup was her fault for being miserable all the time, hating her job, flagrantly flirting with other men, and taking Bill for granted. She noted frequent suicidal thoughts, which she had previously had during high school when her boyfriend broke up with her. In this crisis she had overdosed on over-the-counter medication but induced vomiting because she was too "chicken" to go through with it. Jen assured Alice that she could help her, but they would have to focus on the suicidality as the first order of business (Jen was trained in CAMS at the counseling center and had used it many times with students).

In their first session of CAMS, Jen asked Alice for permission to have a seat next to her to complete the first page of the SSF. This initial assessment provided different rating scales and a chance to write out in her own words things that she was feeling (e.g., what she found was most painful: "... that I ruined my only chance at happiness with Bill"). When asked about reasons for living, Alice noted her parents, her sister, and her dog; in turn reasons for dying centered on never getting married, never having a family, hating her job, and ending the pain. Alice was asked to rank order certain constructs and candidly responded to additional assessment questions about her current suicidal thoughts and history, along with other questions. Jen seemed particularly concerned about Alice's recent heavy alcohol use and lack of sleep.

As they addressed the treatment planning section, Jen asserted that her goal would be to work with Alice on an outpatient basis if at all possible – this surprised Alice as she expected Jen would push for an inpatient admission. But instead, they carefully worked the CAMS Stabilization Plan, and Alice agreed to hand over her stash of pills to her sister for safe keeping. As their first session came to a close, Alice identified the two problems that put Alice's life most at risk – what Jen called suicidal "drivers." Alice noted her hopelessness about ever getting married and having a family and her hatred of her job. Jen assured her that she had various ideas about how they might best treat these problem drivers. Thus, armed with her Stabilization Plan and copies of the SSF they completed, Alice felt a glimmer of hope in the midst of her despair.

The CAMS Philosophy of Care

The CAMS approach to working with patients who are suicidal emphasizes four philosophical "pillars" of care that guide and shape clinical interactions over the course of care. These include empathy, collaboration, honesty, and being suicide-focused.

Empathy

A central component of the CAMS philosophy of care is empathy with the patient's suicidal struggle. Gaining a deep appreciation for what brought the patient to their current suicidal state is a necessary first step for engaging in the CAMS therapeutic framework. CAMS clinicians express this empathy throughout the course of treatment using nonjudgmental language. Importantly, empathy for the patient's suicidal struggle does not mean the clinician endorses relying on suicide as a means of coping. Taking this approach validates the patient's experience and allows them to open up and share about their struggle and ultimately what is driving their suicidal thoughts, feelings, and behaviors. In order for the dyad to get to the root of the "suicidal drivers" in CAMS, empathy creates a kind of door into the patient's inner struggle – the phenomenology of their consideration of suicide. Leading with

“empathic resonance” enables the provider to become a “therapist participant” who can enter into the patient’s inner world [14]. Through sensitive exploration of this inner struggle, the dyad can better identify the drivers of why the patient considers suicide. Based on clinical research, clinician-guided empathy is critical to positive treatment outcomes within CAMS-guided care [28].

Collaboration

Fostering collaboration between the clinician and patient is central to using CAMS – indeed, it is in the name. From the initial implementation of CAMS through outcome disposition, collaboration between clinician and patient is weaved into each and every step of the treatment process. The clinician and patient work together to get to the root of the patient’s struggle with suicide and to identify how to best address the current suicidal crisis the patient is facing. With the clinician’s guidance, CAMS patients are empowered to process through the how, what, when, where, and why of their suicidal thoughts, feelings, and behaviors. Both the clinician and the patient learn more about the patient through this collaborative process as they intentionally explore the patient’s “relationship” with their suicide. Much of the assessment and treatment planning work done in CAMS literally uses a side-by-side seating arrangement (with the patient’s permission), which communicates: we are on the same team. Suicidal risk is objectified, deconstructed, understood, and treated in a direct manner relying heavily on the therapeutic alliance which is built through the ongoing collaborative engagement of CAMS. The collaborative dynamic is meant to empower the patient to embrace their ability to understand and directly inform their own suicide-focused treatment plan [12] as the patient serves as a figurative “co-author” of their treatment.

Honesty/Transparency

At the heart of CAMS remains a commitment to being honest and transparent with patients. Candidly acknowledging that patients are capable to take their own life is a simple truth that often can reassure a skittish patient who is concerned about their “right” to suicide. In the same spirit, CAMS clinicians are candid about legal requirements to stop clear and imminent suicidal risk as a jurisdictional duty of a licensed provider [16]. By talking openly and transparently about the “rules of the road” so to speak, there can be an understanding struck within the therapeutic relationship about how the dyad may navigate around potential power struggles that may arise about imminent risk and the prospect of hospitalization. Ideally, CAMS is used on an outpatient basis with an expressed desire to keep the patient out of inpatient care if at all possible. These open and honest viewpoints and psychoeducation have been found to invariably strengthen the therapeutic bond. The clinician can acknowledge the patient’s ability to end their life without endorsing it as their best option and be plain about their desire to do what it takes not only to

prevent the patient's suicide but also to pursue a life worth living (the final stage of CAMS).

Suicide-Focus

Finally, CAMS does not approach suicide using the same conceptualization as many of the prevailing psychotherapy models. This conceptualization often places the focus of treatment on a patient's mental disorder, relegating suicide to symptom status with the presumed effectiveness of treating the diagnosis (which has little to no support within randomized controlled trials of suicide-effective treatments). Within the CAMS therapeutic framework, *suicide* is the main focus of care – independent of psychiatric diagnosis because suicide serves a functional role for patients [13]. In other words, the prospect of suicide often functions as a coping mechanism or as a problem-solving tool to meet a need for control or to end suffering. The ultimate treatment goal of CAMS is to identify what is driving a patient toward suicide. The effort to identify patient-articulated suicidal drivers leads to pragmatic treatment planning to address and ameliorate these problem drivers, therefore rendering suicide functionally obsolete. From a patient-centered perspective, making patient-defined suicidal drivers the center of treatment validates the patient's experience and care and then addresses those problems that put their life in peril. In CAMS, guided care drivers do not have to be 100% eliminated for progress to be made; managing and coping differently are the key to CAMS-guided recovery. Thus, CAMS provides a way for the dyad to move forward with a patient-centered approach to suicide-specific care, enabling the patient to cope differently and better and creating the prospect of ultimately pursuing a life worth living with purpose and meaning.

Using the Suicide Status Form (SSF) to Guide Clinical Care

As described in the opening case example, the Suicide Status Form functions as a multipurpose assessment and treatment road map of sorts. There are three versions of the SSF that cover the full course of care: the first session, all interim sessions, and the final outcome disposition of CAMS. Every CAMS session at all three phases of care begins with the patient completing the “SSF Core Assessment” ratings (in reference to their psychological pain, stress, agitation, hopelessness, self-hate, and overall behavioral risk of suicide). And every CAMS session across all three phases of care ends with a collaborative treatment planning discussion.

The First Session of CAMS

As a general matter, the first session is believed to be crucial to launching a trajectory for successful care. As seen with the case example of Alice, there are some surprises

in the first session of CAMS in terms of what many patients expect to happen in mental health care. The patient gets center stage in CAMS, and the clinician's job is to follow their lead both in terms of assessment and treatment planning.

Assessment

The first session of CAMS introduces the use of the SSF that will guide care from beginning to middle to end. The clinician and the patient complete the form together, with the clinician physically taking a seat next to the patient, always with permission from the patient. Using the first session version of the SSF, patients are asked to complete several rating scales, qualitative assessments, and rankings of constructs related to their suicidality. As noted earlier, the SSF Core Assessment includes rating of key suicide-related variables; beyond rating the constructs on 5-point scales, the patient is also prompted to write out their feelings of pain, stress, etc. and to rank order their respective importance. Patients then rate whether their suicidal struggle is related to themselves or to others. Next, patients list up to five reasons for living and reasons for dying, respectively, based on importance [15]. Then patients rate their relative wish to live vs. their wish to die using 9-point scales. Section A of the first session SSF ends with the patient identifying and writing out in their own words, "The one thing that would help me to no longer feel suicidal is _____."

Section B of the first session SSF is completed by the clinician, and it evaluates 15 different suicide risk and warning sign variables (i.e., suicide ideation, suicide plans, past suicidal behavior, access to lethal means, etc.). This section remains collaborative but transfers the paperwork back to the clinician to complete. Each variable is assessed by the dyad, and they delve into different considerations relevant to the patient's suicidal suffering that will help inform the treatment plan (including the CAMS Stabilization Plan).

Treatment Planning

Section C of the first session SSF focuses on the development of the CAMS Treatment Plan. Within CAMS-guided treatment planning, three main problems are identified as the focus of treatment. The treatment planning process begins with Problem #1, centered on the patient's self-harm potential and the related development of the CAMS Stabilization Plan (CSP). The CSP serves a key role in the dyad's ability to work on an outpatient basis by first identifying and reducing access to lethal means, establishing a list of five coping strategies and resources for reaching out for help, noting relational support, and identifying and problem-solving any potential barriers to treatment. Problems #2 and #3 of the treatment plan are called direct drivers of the patient's suicidality, which the patient identifies as problems that compel them to consider suicide (a romantic breakup or a serious financial crisis). The CAMS provider supports and guides the discernment of problem drivers, but the drivers should come directly from the patient's perspective. The dyad then lists the goals and objectives for the two problems listed as well as potential interventions for each problem. CAMS clinicians are encouraged to use various techniques, evidence-based approaches, and other strategies they know to target and treat driver problems. In this regard, treatment is not prescribed – it is up to

the clinician as to how they best aim to treat the patient-articulated drivers. Treatment planning ends when the patient verifies that they understand and agree with the plan. At this time, the clinician makes a summary clinical judgment as to the presence of imminent suicide risk (usually based on the quality of the CSP and how on board the patient is with pursuing CAMS on an outpatient basis). Both parties sign the first session SSF, and copies are made for the patient to take with them (or smartphone pictures of the SSF and CSP can serve the same purpose).

It should be noted that at this juncture there is a final page of documentation across all three phases of care which includes key progress note information such as mental status, diagnosis, a judgment about overall suicide risk, and case notes. Many settings where CAMS is used successfully develop policy to make the SSF the official medical record progress note for patients engaged in ongoing CAMS-guided care.

Interim Sessions of CAMS

All CAMS-guided sessions between the first session and the outcome-disposition session are called interim sessions in CAMS. For these sessions, the SSF tracking/update version is used repeatedly throughout interim care. These sessions begin with assessment and end with treatment plan updating.

Assessment

At the start of each interim session, the clinician presents the patient with the SSF Tracking/Update Interim version of the tool and the patient quickly completes Section A of the SSF Core Assessment of the form. Section A includes six self-reported rating scales that make up the SSF Core Assessment (Psychological Pain, Stress, Agitation, Hopelessness, Self-Hate, and Overall Risk of Suicide) and three additional yes/no questions assessing whether the patient had suicidal thoughts or feelings in the past week, was able to manage these thoughts and feelings in the past week, and was engaged in any suicidal behavior in the past week. Upon completion of Section A, the patient and clinician will review the patient's SSF Core Assessment ratings. Reviewing this assessment each session gives the clinical dyad an opportunity to monitor any progress or setbacks throughout the course of the treatment, something that many clinicians and patients find helpful. Continuous review and discussion of the patient's most current ratings on the SSF Core Assessment can not only aid the clinician in case conceptualization, but it can also help inform treatment planning and provide a natural segue to the discussion of the CAMS Stabilization Plan during each interim session. Consequently, following the completion of Section A, the dyad shifts their focus to suicidal drivers which are the focus of interim sessions.

Focus of Care

The treatment focus of all interim sessions of CAMS revolves around treating, managing, and addressing the patient's suicidal drivers. This signature feature of

CAMS is different from typical treatment approaches, wherein treatment is primarily based on the clinician's judgment and observations and focused on treating mental disorders with the presumption that suicidal thoughts and behaviors will be impacted. However, clinicians in CAMS-guided care never presume that a mental disorder is necessarily the cause of a patient's suicidal thoughts and/or behaviors. Rather, CAMS-guided care emphasizes the overarching importance of focusing on what the patient says causes their suicidal suffering. For example, for a patient feeling like they must end their life due to childhood trauma and a current financial crisis, CAMS treatment might employ exposure therapy for the trauma and help the patient receive advisement on financial literacy. In a different patient with drivers of imminent collapses of their marriage and seemingly uncontrollable anger, CAMS-guided care might help the patient and their spouse engage in couple's therapy while using breathing techniques, mindfulness, or anger management to address the latter driver.

Suicidal drivers within CAMS-guided care are of two types: direct drivers and indirect drivers. Direct drivers (i.e., Problems #2 and #3 within CAMS treatment planning) are problems and issues that are idiosyncratic to the patient's suicidal struggle. These drivers include various thoughts, feelings, and behaviors that may compel the patient to consider suicide and may trigger an acute suicidal episode. Patients are not typically suicidal 24 h a day/7 day a week – suicidal states tend to wax and wane. It follows that when direct drivers are triggered or activated, it may spur the patient down the road of suicidal coping. The notion of indirect drivers in CAMS speaks to issues, stressors, or certain situations that may make the patient more vulnerable to the activation of their direct drivers. Examples of indirect drivers are lack of sleep, fighting with close friends, homelessness, unemployment, insomnia, or even mental illness. By definition these indirect drivers do not make the patient actively suicidal, but they can set the stage for the direct drivers to kick in thereby making suicidal coping compelling. Indirect drivers can make a patient feel vulnerable to either the insidious or sudden activation of direct drivers that may engender a potential acute suicidal crisis. As a general matter, CAMS-guided care primarily focuses on direct drivers but if an awareness that a lack of sleep and social isolation (examples of indirect drivers) has often preceded an acute suicidal episode that is good to know from a therapeutic standpoint.

Within CAMS there is often an explicit goal to “sharpen” direct drivers through reflection and discussion over the course of care. This is exactly why the treatment plan is updated at the end of every CAMS session. Discovering in session four that a direct driver about not trusting others may be linked to severe childhood abuse might lead to an evolved driver focused on treating the abuse to help build trust in others.

As noted, within CAMS the treatment of suicidal drivers is up to the clinician, and the approach does not promote any specific interventions or treatment approaches. In this way, clinicians are encouraged to use clinical strategies that they know over the course of interim care. As long as the clinician focuses the intervention on targeting and treating patient-defined suicidal drivers during the interim sessions, they are being adherent to the CAMS framework. Thus, CAMS is problem-focused and flexible rather than strategy-focused and rigid.

Treatment Plan Update

As noted, interim CAMS care focuses on driver treatment, but the treatment is typically dynamic and ever changing, which is why there is a need to revisit the CAMS Treatment Plan at the end of every session. Therefore, the dyad once again takes side-by-side seating to update the CAMS Treatment Plan, which is Section B of the SSF Tracking/Interim Session version of the tool. The team will usually revisit the effectiveness of the CAMS Stabilization Plan and modify it if necessary. They will then reassess the problem drivers and evaluate whether the existing drivers remain the same or have evolved in some way since the last session. Suicidal drivers may remain consistent over the full course of the treatment. However, sometimes drivers change or evolve over time. It is therefore crucial that the clinician does not assume that the patient's suicidal drivers remain static. Rather, the treatment planning process should be dynamic and focused on the root causes of what makes suicide compelling to the patient. Following the reexamination of the problem drivers, the dyad updates the related Goals and Objectives sections as well as the Intervention and Duration sections of the SSF. As in the first session, both parties sign the SSF Tracking/Interim Session form indicating that they concur with the information recorded on the form, and the patient receives a photocopy or takes a picture of their interim SSF document. After each interim session, the clinician will independently and quickly complete Section C of the SSF Tracking/Interim Session form that addresses mental status, diagnosis, overall risk, and case notes. The extensive documentation inherent in CAMS reflects competent and thorough practice and has the side benefit of helping reduce the risk of malpractice liability, as documentation is so critical to the process of litigation.

In addition to the SSF Tracking/Interim Session document, there are other optional tools that CAMS clinicians may employ within interim care. For example, the CAMS Therapeutic Worksheet (CTW) is a tool that helps clarify the patient's history with suicide as well as better understand the nature of their direct and indirect drivers. The CTW helps the patient conceptualize their suicidality using a flow diagram to serve as a visual aid as to how indirect drivers may have created instability and vulnerability and consequently set the stage for the activation of direct drivers pushing the patient to consider suicidal coping. The CTW can be an effective tool that further deconstructs and elucidates patient's relationship with suicide and what they can do to cope differently (e.g., *when* they should know to use the CSP to avert an escalation of suicidal risk).

Case Example Interim Care

CAMS interim care with Jen focused on Alice's obsession with getting married and having a family – she acknowledged that she did not really love Bill; he was really a best friend and would have been a devoted husband and father. Using cognitive therapy Jen focused on Alice's distorted thinking (e.g., that she would “never have a

husband and children”), and they set behavioral goals to gently try out online dating (something Alice swore she would never do). She also referred her to a colleague for a vocational assessment, and based on the results, they agreed that physical therapy was not a good match for her vocationally. Alice’s beloved sister actually attended her fifth session, and there was a discussion about Alice working with her sister in her successful real estate business. With these developments Alice found herself thinking less and less about suicide, and she had successfully used her Stabilization Plan when she Facebook “stalked” Bill who posted pictures of himself with another woman.

Final Session of CAMS

There is not a prescribed number of CAMS interim sessions. Rather, there are as many interim sessions as needed to make therapeutic headway to ideally achieve resolution or other treatment outcomes. Specifically, the patient meets resolution criteria when their ratings of overall risk are a 1 or 2, and they have been able to successfully manage their suicidal thoughts/feelings along with no suicidal behaviors for three consecutive sessions. While there is no set recommended number of sessions, various clinical trials have shown that resolution of suicide risk usually occurs within 12 sessions [18] and many cases resolve in 6–8 sessions of care [4, 20, 25].

Assessment

CAMS-guided care thus concludes when the previously noted resolution criteria are met, which is noted on Section A of the outcome-disposition version of the SSF. Practically speaking, when CAMS patients are on the cusp of resolution with criteria met in a second consecutive session, the patient is made aware that the end of CAMS may occur if these criteria are met by the next session. That said, sometimes the dyad may decide to wait to resolve CAMS based on their desire to ensure that ending CAMS feels right.

In the penultimate session prior to the resolution session, it is wise to engage the patient in a full discussion of their treatment outcome and the patient’s disposition. Once again, this direct discussion of treatment disposition with the patient further emphasizes the collaborative nature of the treatment and gives the patient an opportunity to incorporate their voice into what happens next after CAMS has been brought to an end. In these final sessions, there is a golden opportunity to take stock of what has been learned and to reflect on what would help make the patient’s life more worth living; an overt discussion of how to find more purpose and meaning in a post-suicidal life invariably serves the patient well [12].

Sometimes it seems that care is approaching resolution only for there to be a setback where suicidal risk reemerges. In such situations the model can be reasserted, and the resolution clock can be reset. CAMS clinicians should always be patient, understanding, and supportive about how the CAMS clinical resolution plays out, and not rush or pressure the patient into resolution prematurely.

The Outcome/Disposition Final Session version of the SSF has three separate sections. Similar to the Interim Session version of the SSF, Section A of the Final Session form includes the SSF Core Assessment accompanied by the three yes/no questions assessing the presence of suicidal thoughts, feelings, behaviors, and the patient's ability to manage the thoughts and feelings. If indeed CAMS is being resolved, two additional open-ended questions are addressed asking the patient to specify any aspects of the treatment that were particularly helpful. In addition, there is a query about what they have learned from their care that they could use if they were to experience another suicidal episode. The two outcome questions were adapted from the National Institute of Mental Health (NIMH)-funded Collaborative Study of Depression [8] and help generate discussions about the patient's clinical accomplishments and potential relapse-prevention resources.

Outcome Disposition

Section B of the Final Session SSF is completed by the dyad noting the range of possible clinical outcomes and what – if anything – lies ahead for the patient in terms of their disposition. The patient should receive a copy or take a picture of the final SSF for their own use. There is a final Section C for the clinician to complete the documentation of the case that addresses the patient's mental status, diagnosis, overall risk, and final case notes.

Obviously, the optimal clinical outcomes in CAMS-guided care are suicide-specific treatment-based outcomes and include no completed suicide or suicide attempts, the elimination of suicidal ideation and reduction of symptom distress, and the development of alternative ways of coping. For cases in which suicide was resolved, one potential disposition after CAMS could be continued psychotherapy with the clinician (or a referral) to address any other existing issues in the patient's life. Once suicidal risk has been resolved, the patient might be in need of other specialized treatment (e.g., group therapy). Thus, making an effective clinical referral could potentially be the optimal outcome, helping the patient receive the care that they need and deserve. Another positive outcome is the mutual termination of psychotherapy as CAMS-guided care comes to an end. For certain patients, a short-term course of care to effectively recede suicide is enough for them to proceed in life.

But of course, not all outcomes are desired – some patients drop out or need to be hospitalized. For patients who drop out or choose to discontinue care, reasonable efforts can and should be made for them to re-engage or be offered referrals and/or resources. In any case, the full range of outcomes can be fully documented on the final version of the outcome-disposition SSF.

Suffice it to say, no suicide treatment is perfect and compatible for every single patient. And no matter the level of expertise or amount of effort, no clinician can guarantee that a patient who is suicidal will always be successfully treated and never attempt or even die by suicide. Nevertheless, the CAMS framework is a proven and reliable, evidence-based, and suicide-specific treatment that provides the basis for ensuring the best possible care for patients who are suicidal. Its use can ensure that

excellent suicide-specific care has been rendered, and the extensive SSF documentation reflects that care and decreases one's exposure to malpractice liability should a fatal outcome occur.

Case Study Outcome Disposition

Alice met criteria for CAMS resolution by session 8, but they delayed resolving until session 10 when Alice felt confident that suicide was no longer a viable option for her. Alice had some success with online dating; having had a few lunches with a couple of men, she left guardedly hopeful that she could perhaps meet someone to marry one day, but she told Jen that she wanted to take the pressure off herself and take things slow. One major decision was to quit her physical therapy and to start working with her sister in real estate. By resolution of CAMS, she was taking online courses to take her real estate exam in the coming months. Alice and Jen continued to meet in psychotherapy after CAMS for about 6 months, at which point Jen referred Alice to a group therapy run by a colleague that Alice found extremely helpful.

Empirical Support for CAMS

The empirical support for CAMS and the use of the SSF are extensive, replicated, and still growing. There are now eight published correlational/open trials and five published randomized controlled trials demonstrating the effectiveness of CAMS.

SSF-Focused Studies

Currently, CAMS-guided care and the SSF are used in a wide range of clinical settings in the United States and around the world. The effectiveness and efficacy of CAMS and the SSF in clinical settings are increasingly supported by a line of ongoing correlational and randomized controlled trials (RCTs). There is also clear evidence supporting the psychometric validity and reliability of the SSF Core Assessment [3, 5, 17]. One of the first studies of CAMS was conducted in 1997 by Jobes and colleagues in an outpatient setting. This was a psychometrics study of the SSF conducted with a sample of 106 college students who were suicidal and seeking treatment at a university-based counseling center [17]. The results from this study indicated that the six items on the SSF Core Assessment (Psychological Pain, Stress, Agitation, Hopelessness, Self-Hate, and Overall Risk of Suicide) operate quasi-independently, have good to excellent convergent and criteria-prediction validity, and have moderate to good test-retest reliability. Results from subsequent psychometrics studies of the SSF Core Assessment indicate that the SSF is psychometrically sound among psychiatric inpatients who are high risk and suicidal [5] and teenagers who are suicidal [3].

Correlational Clinical Trials

A second study from 1997 with college students who were suicidal by Jobes and colleagues examined treatment-related outcomes of CAMS. The findings from this within-group pre-/posttreatment study revealed a significant decrease in the patient's self-reported ratings on the SSF Core Assessment over the course of the treatment. Additional analyses utilizing multilevel modeling also found a significant decrease in overall symptom distress and suicidal ideation from pre- to posttreatment [19]. Further examination of the clinical utilities of CAMS was also conducted at two US Air Force outpatient mental health clinics [18]. The results from this archival data analyses revealed that CAMS-guided care was associated with reducing suicidal ideation significantly more than treatment as usual (TAU). Findings also indicated that CAMS patients had significantly fewer emergency department visits and medical appointments than TAU patients in the 6 months after the start of suicide-related mental health treatment.

Although CAMS was initially developed for outpatient use, it has been adapted and used in a series of inpatient trials at the Menninger Clinic, a psychiatric inpatient hospital setting. In one naturalistic study at Menninger, 20 patients who were suicidal and high risk received CAMS showing significant statistical and clinical reductions in hopelessness, depression, suicidal ideation, suicidal-relevant cognitions, as well as reductions of the SSF Core Assessment when comparing admission ratings vs. final treatment ratings [9]. Two subsequent quasi-experimental studies were conducted at the Menninger Clinic using propensity score matching to compare a group of patients receiving CAMS vs. patients receiving TAU [10, 11]. The comparison of CAMS to TAU in these two studies found patients in CAMS improved significantly better than TAU on a wide range of outcome measures (i.e., suicide-related cognitions, levels of depression, suicidal ideation, functional disability, and well-being) [10, 11].

Randomized Controlled Trials of CAMS

Although many correlational studies in naturalistic settings have established robust external validity of CAMS, more recent clinical studies of CAMS have focused on RCT designs in order to further enhance internal validity and examine the *causal* impact of CAMS. The first RCT was a feasibility study comparing CAMS to “enhanced care as usual” (E-CAU) with a sample of outpatients who were suicidal [4]. In this study, 32 participants were randomly assigned to CAMS or E-CAU in an outpatient mental health treatment clinic within a larger medical center. Despite the limited statistical power with the small sample size, there were significant findings for primary and secondary outcome measures showing the superior effectiveness of CAMS-guided care in terms of reducing suicidal ideation, reducing overall symptom distress, and increasing hope. More importantly, the most robust between-group difference was detected at 12 months after the start of the treatment,

demonstrating the possible enduring impact of CAMS many months after treatment ended.

Additional RCTs comparing CAMS with E-CAU or TAU have been conducted in two larger outpatient studies, one with 148 US Army soldiers who were suicidal [20] and another with 62 college students who were suicidal [25]. In the US Army study, participants in the CAMS condition were significantly less likely to have any suicidal ideation at 3 months after baseline assessments. Specifically, at the 3-month follow-up, only 37% of participants in the CAMS condition reported any suicidal ideation compared to 61% of participants in the E-CAU condition. When comparing TAU with CAMS in a RCT with college students who were suicidal, CAMS was found to have a significantly positive impact on depression, hopelessness, and suicidal ideation throughout the course of the treatment and especially among students who were suicidal but less complex (i.e., those without a multiple suicide attempt history or borderline personality disorder features) when comparing to TAU [25]. Finally, in a RCT comparing CAMS to dialectical behavior therapy (DBT), a treatment for self-injurious behaviors supported by extensive empirical literature, no statistically significant between-group differences were detected between CAMS and DBT for non-suicidal self-injury and suicide attempts [1]. It is important to note that this study was underpowered and CAMS impact on self-harm and suicide attempts was trending somewhat better than DBT, which is by far the most proven treatment for reducing self-harm and suicide attempts [6].

Several studies conducted outside of the United States have also validated the cross-cultural utility of CAMS and the SSF. Two naturalistic studies from Denmark with a range of patients who were suicidal in outpatient community mental health settings have demonstrated the feasibility and clinical utility of CAMS and have further shown statistically significant pre-/post changes on all SSF Core Assessment items [2, 24]. Additionally, 74–80% of the participants in the two studies expressed that CAMS was the main factor in eliminating their suicidality. Furthermore, a more recent RCT from Norway with patients who were suicidal in inpatient and outpatient care found that CAMS outperformed TAU at the 6-month follow-up. After 6 months, patients in the CAMS condition reported lower levels of suicidal ideation. Moreover, patients in the CAMS condition also experienced greater reductions in general mental health distress at the 6-month and 12-month follow-ups [26].

In summary, results from a vast number of correlational and randomized controlled trials (RCTs) have supported the effectiveness and efficacy of CAMS and the SSF in multiple clinical settings with patients of different backgrounds. Future studies of CAMS will continue to endeavor to empirically validate CAMS in RCTs and experimental replications.

Other and Ongoing CAMS-Related Research

Although the accumulation data to date overwhelmingly supports the effectiveness of CAMS in reducing suicidal risk, additional CAMS-related research studies are currently underway to further validate and replicate the empirical support for CAMS

in different clinical settings and among diverse groups of patients who are suicidal (e.g., children and adolescents). One such study is the Aftercare Focus Study, a RCT of 150 participants comparing the effect of CAMS to standard care on suicidal ideation and future suicide attempts. Other RCTs are also in progress at the San Diego VA medical center and in an inpatient facility in Germany [27]. Furthermore, a large-scale multi-site study across several college counseling centers in the United States examining treatment effects of CAMS and DBT on 700 college students who are suicidal is just beginning. Other CAMS-related research includes the adaptation and creation of a CAMS-inspired virtual platform for patients who are suicidal in emergency departments [7], as well as the development of an electronic version of the SSF (e-SSF) that can import key medical record data into electronic health records. Finally, feasibility clinical trials comparing a group version of CAMS (CAMS-G) with veterans who are suicidal are underway.

Conclusions and Next Steps for CAMS

CAMS is a proven patient-centered framework that can be used across a range of clinical settings with different types of patients who are suicidal [21]. Current efforts are underway to use CAMS within a telehealth modality [23] and to further evolve the electronic use of the SSF. Future clinical trials will establish the effectiveness of CAMS for teens and children who are suicidal [22]. CAMS is thus providing clinical relief to a range of patients who are suicidal, offering a treatment focused on their suicidogenic problems with the ultimate goal of giving the patient a life worth living beyond the specter of suicide.

Abstract

A clinical differentiation model of suicidal behaviors may improve clinical practice. It may be helpful to determine which type of treatment is most appropriate for subtypes of suicidal behaviors and may improve adherence to suicide prevention guidelines. Also, differentiation of suicidal behaviors may create clarity about the role of healthcare providers, patients, and social networks in the prevention of completed suicide. From clinical experience, we developed a new model to differentiate subtypes of suicidal behaviors, the hypothetic four-type model of entrapment (H4ME), distinguishing the origin of entrapment that may result in a suicidal state. The subtypes are (1) perceptual disintegration (PD), (2) primary depressive cognition (PDC), (3) psychosocial turmoil (PT), and (4) inadequate communication/coping (IC) (emphasizing emotional pain). The SUICIDI-questionnaire was designed to identify subtypes of entrapment. In this chapter, we briefly describe previous models of subtypes of suicide, the

Introduction

While suicidal behavior is common, suicide, the “end-product” of suicidal behavior, is rare. For example, in the Netherlands approximately 400,000 people per year experience suicidal thoughts. There are about 96,000 suicide attempts and around 1,850 people end their lives [1]. This means less than 0.5% of people experiencing suicidal thoughts ultimately end their lives. Because of the enormous impact of suicide thoughts, there is more attention and focus for suicide than for the more common suicidal behavior.

Clinical differentiation of somatic disorders is common, for example, the differentiation and classification of breast cancer [2], diabetes [3], dementia, [4], etc. Differentiation and classification of disorders have resulted in improved diagnosis, more effective treatment, and targeted counseling strategies. Suicidal behavior is complex and multilayered; it never occurs in isolation because there are always several factors at stake. Except for a distinction between suicidal behavior with or without attempt or between acute and chronic suicidal behavior, general guidelines, scientific research, and general texts about suicidal behavior do not differentiate suicidal behavior. Still, it continues to be defined as a uniform concept [5–7].

When it comes to treatment or management of suicidal behavior, risks assessment for suicide is extremely difficult. Even though some predictive, treatable factors are known, the main emphasis seems to be on treatment of underlying psychiatric illness and general safety planning rather than on the suicidal process that may lead to suicide. Suicidal behavior occurs in a variety of psychiatric disorders [8], but only for borderline personality disorder and/or major depressive disorder suicidal behavior is one of the possible symptoms required to meet the DSM classification criteria. There is some knowledge and evidence of effective, specific forms of psychotherapy and biological treatments for suicidal behavior [9]. However, we observe a discrepancy between knowledge and the practical application of what we know. Theoretical results from neuroimaging, research into genetic vulnerability for suicide and psychiatric research into suicidal behavior, for example, are often difficult to apply into practice.

Mental health services have extensive knowledge and experience with suicidal behavior and are almost automatically expected to manage people presenting with suicidal behavior.

The matter of professional responsibility and liability is extremely complex whether it is about collective responsibility or individual responsibility of members

of a mental health team or other caregivers. Responsibilities of professionals are partially determined by the way people with suicidal ideation present themselves to services. Taking into consideration that in the Netherlands, 60% or less of the people who end their lives were not known to mental health services [10], we might wonder whether specialist services should be solely responsible for managing suicidal behavior. Inpatient units can admit patients when a community team is unable to manage the risks; however, admission is also an opportunity to shift the risks from the community to the inpatient unit. It is a misconception that an inpatient unit is better able to keep a patient safe; however, the effectiveness of admission is not known. We do know though that admission is not a determining factor for the ultimate suicide risk and can even lead to iatrogenic damage both on the short and long term [11, 12]. Management of suicidal behavior by non-specialist services – who may not have the extensive knowledge and support system to fall back on – is not straightforward and this will raise further questions about issues around responsibility. The complex dynamics and the risks resulting from suicidal behavior may lead to formalized and restrictive, “defensive” practice.

Theoretical typologies are useful in generating new hypotheses about suicide risk, treatment, and prevention. Classical, contemporary, and empirical typologies of suicide have been established (see for an overview [13]). A well-known example of classical typology is Emile Durkheim’s model that distinguishes

1. Egoistic
2. Altruistic
3. Anomic
4. Fatalistic suicide

Durkheim compared suicide rates for various groups (e.g., Protestants and Catholics, soldiers and civilians) and put in place a theory of suicide deduced from the influence of social forces. He argued that suicide rates are a reflection of the degree to which individuals were integrated into and regulated by society [14]. An example of a more contemporary typology of suicide is the psychodynamic conceptualization of suicide, based on “cessation,” defined as “discontinuation of capacity for any further conscious experience” [15]. Shneidman used the term “psyde” to represent cessation and delineated four subtypes of suicidal individuals:

1. Psyde-seekers
2. Psyde-initiators
3. Psyde-ignorers
4. Psyde-darers

Empirical studies on typologies of suicide [1, 16–21] were conducted when more comprehensive statistical methods became available. Risk factors for suicide, identified in epidemiological studies, served as (sets of) variables to quantify typologies. For example, Reynolds and Berman (1995) attempted to distract the major subtypes of suicide previously reported in the literature and empirically reduce them to a

useful number. They identified significant overlap between typologies proposed by earlier theorists and simplified them into five distinct subgroups [16]:

1. Depression/low self-esteem
2. Escapist
3. Aggression
4. Confusion
5. Alienation

The identification of typologies of suicide has been useful to formulate theories to explain suicide, such as the cry of pain (CoP) hypothesis [22], the interpersonal theory (IPT) [23], and the escape from self model – which extends existing theories of escape and arrested flight [24]. We need however to bear in mind that theoretic types of suicide do not clearly discriminate between completed suicide and non-fatal suicidal behaviors. A relatively new approach in this context is the integrated motivational-volitional model of suicidal behavior [25] aiming at making a distinction between persons with suicidal thoughts and those who engage in suicidal acts. Even though a differentiation model of suicidal behavior would be helpful to develop and investigate successful treatment strategies, no clear differentiation systems for “suicidal behaviour” are available [13].

The common, unpredictable, unstructured, and risky presentation of suicidal behavior in clinical practice and the lack of structure and differentiation of management and diagnosis of suicidal behavior have been the inspiration and the foundation of the development of a model for clinical differentiation of suicidal behavior: the (hypothetic) four-type model of entrapment (H4ME). Its availability would enable clinicians to develop specific forms of management of suicidal behaviors and may enhance scientific research of suicidal behavior at biological, psychotherapeutic, and social level [8, 26–28, 29, 30, 31]. The H4ME model is purely based on clinical experience and assessments of a diverse range of suicidal presentations in mental healthcare practice. Hence, clinical practice is the starting point of the model’s development.

The Context of Development

The H4ME has been developed in response to the publication of the Dutch multidisciplinary guideline on the assessment and treatment of suicidal behavior [32]. The implementation of the guideline by the Dutch mental healthcare system has been supported by the PITSTOP study [33], a cluster randomized trial, examining the effect of an e-learning-supported train-the-trainer model to train mental healthcare workers in applying guideline recommendations, compared with “the usual” implementation strategy. The PITSTOP training was specifically developed for this study [34] and is based on an integrated model of stress vulnerability [35] and entrapment [36] to explain the onset of suicidal behaviors (Fig. 1), designed and introduced by the authors of the Dutch multidisciplinary guideline [32].

Fig. 1 Integrated model of stress vulnerability [35] and entrapment [36] of suicidal behavior

During the PITSTOP training, mental healthcare workers are trained to assess suicidal behaviors according to the clinical assessment of suicidal episodes (CASE) method [37] (Fig. 2), a four-step interview for the assessment of suicidal behavior. First, the current suicidal condition is examined to estimate the likelihood of completed suicide at the time of the interview. Second, stressful events contributing to the onset of the suicidal behavior are examined. Third, vulnerability and protective factors for suicide are assessed, and fourth, the patient's prospects of the future are addressed. The extent of entrapment, the feeling of being trapped and the cognition that escape is only achievable through death [36] are established by looking at the outcome of the first (current suicidal condition) and the last step (the patient's view of the future) of the CASE interview. For example, a patient who is an immediate risk of suicide and cannot see a future or an improvement of his situation is more likely to feel "entrapped" than a patient considering suicide because his wife is insisting on a divorce. On the basis of the CASE interview outcome, an appropriate multidisciplinary treatment strategy is established, for instance by moderating the impact of stress factors or by strengthening factors that protect the patient from getting entangled by the entrapment (Fig. 3).

The PITSTOP training resulted in an increased adherence to the Dutch multidisciplinary guideline compared to usual implementation strategies [38, 39]. The PITSTOP training has become the "golden standard" in the Netherlands when it

Fig. 2 CASE interview [37]

comes to training mental healthcare workers in suicidal behavior assessment and prevention strategies. Over the years, more than 40,000 mental healthcare workers of all professional disciplines were trained by the PITSTOP training. We found that mental healthcare professionals are becoming more familiar with the concept of “entrapment” and more skilled in looking at – and discussing – the pathway to entrapment. These essential skills are learned with the PITSTOP training. Currently, estimating the level of entrapment is the key strategy for assessment of short- and long-term suicide risks in patients presenting to mental health services with suicidal behavior.

The Benefits of Clinical Differentiation of Suicidal Behaviours

We believe that theoretical and empirical typologies of suicide have limited use in clinical practice. First, sets of variables representing a suicide typology may result in an unreliable estimate of the acute suicide risk. Additionally, whether patient factors or social factors increase or moderate the suicide risk depends on the context of in which it occurs [40]. For example, unemployment is a risk factor for a patient who recently lost his job and is a vulnerability factor when long-term unemployment has resulted in depression. When a patient lacks social skills to maintain himself in employment and is entitled to unemployment benefits, unemployment may be a protective factor. Secondly, clinicians are not primarily

Subject	Observing/questioning	Increasing risk	Decreasing risk/protective	
1 Current suicidality	Acuteness of suicide risk	Strong wish to end life	Low intention to die	
		Little control over own actions		
		Pressure to execute suicide plans		
		Perceived burden to others		
		Dichotomous thinking		
		Severe perceived sense of suffering		
		Tunnel vision		
2 Recent stressors	Illness/poor health Impact of life-changing events	Access to means		E
		Psychiatric symptoms	Connectedness with others	
		Substance abuse	Positive therapeutic relationship with mental health professional	Z
		Somatic illness		T
		Loss	Parenthood	R
		Psychosocial stressors	Involvement with religious organization	A
		Humiliation		P
3 Protective factors	Personality characteristics History of suicidal behavior Extent of social support Minimum needs for fulfilment have been met	Impulsivity		
		Lack of problem-solving skills		M
		History of suicidal ideation		
		History of suicide attempts		
		Family history of suicidal behavior		E
		Reduced sense of meaning		Z
				T
4 Future planning	Can see improvements and change for the better	Strong wish to end life	Expectation that things will change or improve positively	
		Lack of control over behavior		
		Pressure to execute suicide plans		
		Burden to others		
		Dichotomous thinking		
		Experience of severe suffering		
		Tunnel vision		
		Access to means		

Fig. 3 Theoretical aspects of the CASE for the assessment of suicidal behavior

interested in future suicide risks, but mostly want to know how to act to prevent suicide when assessing the immediate suicide risk. This may explain why international guidelines [41–43] do not distinguish between types of suicidal behavior.

We notice that a practical rather than a theoretical approach to management of the presenting behavior would be preferable for clinical practice. The presented H4ME model is a practical way to create order in the complexity of suicidal behavior. It distinguishes between different presentations of suicidal behavior and makes it easier for all stakeholders to assess this. The model supports clinicians to decide on the most appropriate, evidence-based management of suicidal behavior and allows a critical appraisal of roles and responsibilities of all stakeholders involved (the community, specialist, and non-specialist health services, neighborhoods, patients, relatives of the patient) in a practical and non-judgmental way. We assume that this will result in a change in dynamics and allow for best practice solutions and more evidence-based treatment.

The Hypothetic Four-Type Model of Entrapment (H4ME)

The Dutch multidisciplinary guideline [32] distinguishes between chronic suicidal conditions and acute suicidal conditions [44]. Van Luyn states that chronic suicidal behavior can be part of a diagnostic feature of borderline personality disorder. A

patient with a borderline personality disorder may become acutely suicidal in response to a life event or when suffering with a comorbid depression. An increased sense of helplessness and despair may (temporarily) increase the suicide risk. There is a difference in response of mental healthcare professionals to acute and chronic suicidal behavior. While a patient with chronic suicidal thoughts is expected to be able not to act on those thoughts, mental healthcare professionals are expected to protect the person if the suicidal intent suddenly becomes more acute and the risk of suicide increases [45].

Van Luyn's view (2010) inspired us to differentiate "the aetiology of entrapment." Etiology refers to the study of causation and onset of the condition. Looking at typologies as the starting point of the assessment of suicide risks and suicide prevention [13], we set out to develop a four-type model (H4ME) of entrapment rather than a model based on different types of completed suicide. We believe it is possible to categorise any form of suicidal behavior encountered in clinical practice into one of the four types and think that the H4ME is generally applicable irrespective of specific patient features like age, gender, diagnostic category, or any other subgroup feature. However, we cannot rule out that some patient – or environmental – characteristics may be associated with one or more types of entrapment. Additionally, we can foresee that "entrapment types" will need a more specific description or further differentiation. This is currently studied in a validation study [46] (see paragraph 6).

Screening of suicidal behavior will be improved if instruments and procedures are based on a small number of subtypes, and typologies should be based on existing models of suicidal behaviors [13]. The H4EM is based on the theory of entrapment, stating that the more the patient perceives "entrapment," the higher the actual suicide risk [36]. The model is further based on the assumption that suicide risks may vary between patients and within patients over time [32].

First, we will describe the four types of entrapment of the H4ME, and subsequently we will present the SUICIDI-2 classification (suicidal differentiation version 2): a preliminary instrument by which entrapment can be classified in type I, II, III, and IV. Table 1 displays vignettes of the four types.

The H4ME* distinguishes between four types of entrapment etiology:

- I. Perceptual disintegration (PD) – entrapment originated from the context of disturbed perceptions and/or behaviors
- II. Primary depressive cognition (PDC) – entrapment in the context of (a) depressive cognition(s)
- III. Psychosocial turmoil (PT) – entrapment in the context of acute reactivity to a (deemed or actual) loss, offence, adversity, or doom
- IV. Inadequate communication/coping(IC) (Emphasizing Emotional Pain) – entrapment in the context of communicating intense suffering

*Substance abuse and/or somatic symptoms can be viewed as modifiers whose effect depends on the subtype of entrapment (Fig. 4).

Table 1 Vignettes of entrapment typology**Vignette 1**

This case is about a 31-year-old woman, developing suicidal thoughts 2 weeks after delivering her first child, believing her stepfather fathered the child and not the biological father of the child. There is a history of sexual abuse as a young girl, with stepfather as the perpetrator. Patient believes her child will return to the “immaculate universe,” which is – according to the patient – a timeless entity without inequality. Patient has a history of previous psychotic episodes and two serious suicide attempts and except for a partner who is a lorry driver, there is little support and/or network at home

Vignette 2

This case is about a 24-year-old student who is convinced suicide is the only way out in a situation perceived as unbearable and unlikely to improve. He was recently diagnosed with bipolar affective disorder (BPAD) when he presented with a depressive episode, and the suicidal ideation gradually got worse. The patient experiences severe side effects of psychotropic medication and worries about “ending up” like his father, who was also diagnosed with BPAD. Patient sees himself as a failure and cannot foresee himself living his life as a “psychiatric case.” Several members of his family tried to kill themselves when depressed and patient is vulnerable to adopt a similar behavior pattern. Protective factors are fellow students, housemates, and his younger sister who is still living with their parents. He considers himself to be a burden to others and finds it difficult to contain his impulse to hang himself

Vignette 3

This case is about a 47-year-old man who became suicidal after his wife ended the marriage and kicked him out when she caught him watching child porn on his computer. His wife reported him to the police and informed the board of the school where he worked as vice headmaster. Patient ran off with his car and was reported missing for several hours. He was picked up by the rail-track the same evening, waiting in his car for the freight train. He was desperate, thinking he could not continue living out of shame and feared he was going to lose contact with his wife, children and family including in-laws, work and church, just about everything that made his life worth living. Even though his son assured him he would continue supporting his father, patient did not want to face anyone. Patient is convinced he is better off dead and deserves God’s punishment for his behavior

Vignette 4

This case is about a 56-year-old, divorced woman who attempted to take her life by taking 20 tablets of Oxazepam 10 mg and a bottle of wine. Patient warned her daughter after the overdose, who then found her. Reason for the overdose was a comment from her daughter that she thought it was better for patient not to see her grandchildren and patient felt rejected. Half a year ago patient had a CVA, ever since she suffers with a right-sided paralysis and is wheelchair-bound. She is known with alcohol dependency and chronic suicidal behavior and has a history of suicide attempts. Patient tried to kill herself after her other daughter died (1996), her partner (2011), and when her grandchild was diagnosed with neuroblastoma (2014). Patient is angry she did not manage to kill herself and is resentful towards her daughter because she called 999. For her, life is not worth living with physical disabilities and not being able to see her grandchildren

A multidimensional approach, making use of theoretical aspects of different forms of psychopathology and different dimensions of personality deficiencies playing an important role in the different presentations of suicidal behavior, was used for the theoretical foundation of the model. The model includes two clinical subtypes recognizable in clinical practice which are derived from the theoretical model of “affective dysregulation and perceptual disintegration” [47] and dimensions of the Cloninger

Fig. 4 The four subtypes of suicidal behavior and theoretical aspects

model for temperament and character [48] with the “personality deficiency dimensions” of temperament (harm avoidance, novelty seeking, reward dependence, and character) and character (self-directedness and cooperativeness).

SUICIDI-2: An Instrument to Classify Entrapment

The SUICIDI-2 (suicidal differentiation version 2) was designed to assign the entrapment status to type I, II, III, or IV. The SUICIDI-2 should be considered as a provisional description of the four types of entrapment. Over the last 3 years, the ongoing development of the H4ME model and the SUICIDI-2 was presented to psychiatrists, psychologists, and nurses. The H4ME model and the SUICIDI-2 were presented in meetings in the context of suicide prevention in the Netherlands and abroad [46, 49, 50–53]. Those meetings provided feedback of attenders; feedback was processed and resulted in the adoption of new versions. The SUICIDI-2 (and earlier versions) was repeatedly tested to examine its usability; it was discussed and adjusted after thorough discussion among suicide prevention experts during the last 3 years. The model was well received by colleagues and turned out to be suitable in clinical practice. It supports a clearer distinction between different phenotypes of suicidal behaviors and promotes a more tailored management and treatment strategy. The model has been used as a basis to develop a treatment algorithm for suicidal patients to investigate suicidal behavior, as part of the Dutch national suicide prevention policy [52, 54] (Table 2).

Table 2 The SUICIDI-2 classification of entrapment types

Type	Explanation	Description
I	Perceptual disintegration (PD)	0 = not applicable 1 = the suicidal behavior is associated with disturbed perception caused by perceptual disintegration and/or behavior but may also be explained by (an) other cause(s)* 2 = the suicidal behavior is mostly explained by disturbed perception caused by perceptual disintegration and/or behavior* *Probability of psychosis may be explained by a number of contributing factor. For example, a patient developed psychosis with suicidal thoughts while going through bereavement. In this case, psychosis is the cause; a 2 must be scored. This will also be the case when psychosis is triggered by substance use
II	Primary depressive cognition (PDC)	0 = not applicable 1 = the suicidal behavior is associated with depressive, negative thoughts or is related to dreariness, perceived sense of failure or imperfection 2 = the suicidal behavior is associated with depressive, negative thoughts or is related to feelings of depression, failure, or imperfection There is no psychotic symptomatology. The condition does not suddenly occur as a consequence of a negative event
III	Psychosocial turmoil (PT)	0 = not applicable 1 = the suicidal behavior is a reaction to an unexpected event accompanied by a loss. However, the onset of the suicidal behavior may also be explained by (an) other cause(s) 2 = the suicidal behavior is mostly explained by a real or imaginary experience of loss, adversity, or doom. Depressive symptoms may be present but last for less than 2 weeks. Negative cognitions are present, but they do not stem from psychosis. The suicidal behavior is not initiated and used as a tool to convince others to help or change the situation
IV	Inadequate communication/coping (IC) (Emphasizing Emotional Pain)	0 = not applicable 1 = the suicidal behavior is a way to express how suffering has increased the burden and/or the behavior is initiated to convince others to make changes to the situation the clinician has the impression that the patient does not have communicative skills to express their distress. Still, the clinician cannot fully assess whether the suicidal ideation is genuine 2 = the suicidal behavior is clearly used as a way to bring about change, however for others to initiate the change. Depressive or psychotic symptoms are absent

Validation Strategy of the H4ME

Future research into the model may demonstrate that the model is not just applicable in practice but carries scientific validation and evidence. The hypothetical H4ME model has not been validated yet and as such may not cover the whole spectrum of suicidal behavior. Proposed subtypes may overlap or need further differentiation. It is not known yet, whether the SUICIDI-2 will capture the complete range of behavior as encountered within mental health services and may need adjustment. This is why we have initiated the VAMOS-G study the “validatie model suïcidaal gedrag” (validation model suicidal behavior) [7]. The aims of the study are:

1. Determining whether the preliminary clinical model H4ME [52, 54] accurately describes the complete spectrum of suicidal behavior as encountered in specialist mental health services
2. Checking whether the SUICIDI-2 allows classification of the four types as described in H4ME
3. Investigating whether (and how) the SUICIDI-2 needs to be adjusted in order to classify suicidal behavior in four or more types or if there is overlap

Further research may answer the questions we raised and may result in an improvement of the model.

Discussion

Suicide risks vary in severity, which determines the urgency with which it needs to be managed. Suicide risk varies between the different types of entrapment and within the groups of identified patients. Progress varies, the etiology may be different and risks may recur. The model is not a statistical model and one type of suicidal behavior does not necessarily exclude the other. Management of suicidal behavior often depends on management of underlying issues, be it psychological, psychiatric, social, or physical.

Guidelines advise on treatment of comorbid or underlying mental illness and include psychological treatment and support, not just for personality disorders but also in case of inadequate coping skills. Examples are dialectical behavior therapy (DBT) metallization-based psychotherapy (MBT) and transference-focused psychotherapy (TFP) which are all effective for suicidal behavior in borderline personality disorder, achieving a reduction in suicidal behavior [55]. Mindfulness-based cognitive therapy (MBCT) has been shown by several studies to be effective [27], although – looking at the model – we do not know for which kind of suicidal behavior this would work best.

Table 3 describes – per type – features, diagnosis, treatment policy (pharmacological), and follow-up risk assessment; recommendations are based on empirical evidence and best practice.

Another promising way to manage suicidal behavior, focusing on the suicidal process, is CAMS [26, 28]. This method zooms in on the motivational drivers forming the basis of suicidal behavior. The above-named treatments and management of suicidal behavior might work best for the entrapment category of “depressive cognition” but also for Inadequate communication/coping(IC) (Emphasizing Emotional Pain), and more research is needed to find out if differentiation may improve the indication for specific psychotherapeutic treatment.

There is convincing evidence that cognitive behavior therapy is effective for treatment of suicidal behavior [56]. However, does this entail that it is equally effective for all types of suicidal behavior [31]? We are unable to elaborate on all and every form of psychotherapeutic treatment option that is available and need to be very careful about suggesting any, but we do know that the differentiation model may be helpful in allocating specific forms of treatment to specific forms of suicidal behavior.

There is insufficient evidence for the effectiveness of antidepressants, antipsychotics, mood stabilizers, anxiolytics, or ECT for isolated suicidal behavior [29, 57]. Only for clozapine and lithium there is evidence of a relation between reduction in suicidal behavior and psychotropic medication; however, the type of suicidal behavior for which it might be effective has not been specified [9, 58]. Perhaps it will work best for perceptual disintegration.

Hypnotics help to improve sleep for all groups, especially for the “psychosocial entrapment” group. But there is no strong evidence it will help with the reduction of suicidal behavior when there are serious sleep problems and ruminations.

ECT is more effective in reducing suicidal behavior than in reducing other symptoms associated with depression; however, there is still no convincing evidence that it lifts suicidal behavior completely. Perhaps clearer boundaries between groups and improved subtyping of suicidal behavior may generate research into evidence that it may help for the “perceptual disintegration type.” Treatment with ketamine may play a role in treatment of treatment-resistant depression [59] and may especially be effective for the “primary depressive cognition” type.

As mentioned before, the H4ME model may also shed a light on responsibilities. Defensive practice and risk aversion may lead to attempts to shift responsibilities to other services, for example, from the community mental health service to the acute admission ward. This will lead to the emphasis being put on the responsibility of services and not on the best treatment for the patient. The model may help to allocate the appropriate form of care to a specific group and may prevent iatrogenic damage. Admissions for patients with personality disorders or people from the “Inadequate communication/coping(IC) (Emphasizing Emotional Pain)” group may be counterproductive [12]. Ideally, for patients from the “psychosocial turmoil” group, admissions are kept brief. Long admissions may lead to alienation of a patients’ support network, paradoxically worsen the symptoms or increase the stigma.

Research of the effect of admission on suicide either in a locked or open ward does not show convincing effect on the reduction or prevention of suicide. The

Table 3 Subtypes of suicidal behavior and possible relations and hypothetical policy

	Perceptual disintegration	Primary depressive cognition	Psychosocial turmoil	Inadequate communication/coping (IC) (Emphasizing Emotional Pain)
Severity of the suicide risk	++++	++	+++	+
Duration	Days/weeks	Weeks/months	Days	Days/hours; often exacerbation of chronic suicidal behavior
Expected course	Reduction after treatment of psychosis	Reduction after biological and/or psychological treatment	Reduction when tunnel vision decreases Reduces when peak of mourning has passed	Nonspecific reduction within hours/days or when behavior has been exposed or when underlying problems have come to the surface Risk of acute shift to chronic risk and shift to another type
Recurrence	New psychotic episode Triggering of trauma	Recurrent affective disorder	Recurrent episode of psychosocial stress or continuation of severe stress Received “narcissistic” affront	Interpersonal stress and perceived powerlessness Lack of external recognition of underlying suffering
Reassessment of suicide risk	Several times a day Continuous during treatment After recovery With the recurrence of a new episode As precaution during trauma therapy	Several times a day Regularly during treatment After recovery New episode, when the mood deteriorates	Several times a day Ranging from a few times a day to zero In the aftermath of an acute suicidal episode During a new episode of severe psychosocial stress and/or new setback	After the suicidal episode When continued or renewed lack of recognition of underlying suffering During interpersonal stress and perceived powerlessness

Pharmacotherapy	Antipsychotics (clozapine) and/or mood stabilizer (lithium) Possibly additional benzodiazepines in the event of major anxiety	Antidepressant and/or mood stabilizer Restrained use of benzodiazepines when increased risk of impulsivity Short-term benzodiazepines for sleep deprivation	Restrained use of medication Possibly symptom relief for sleep deprivation and/or great anxiety	Hold back medication when possible (changes in or addition to) pharmacological treatment
Actions during crisis	Admission (if needed) Intensive home treatment if risk is acceptable	Emergency care - Intensive home treatment	Short admission	(F)ACT, crisis plan
Follow-up	Outpatient treatment of psychotic symptoms Trauma treatment	Outpatient treatment of depressive symptoms with CBT, CAMS, etc.	General practitioner	(F)ACT Additionally DGT or CAMS or collaborative care, etc. Vigilant for change of symptoms
Responsibility patient	Increasing when disintegration reduces	Increasing when depressive symptoms reduce	Increasing when “tunnel vision” fades	Holding back or taking over control Offer maximum support Recognize emotional suffering

question remains: had a better differentiation of suicidal behavior been available, would the outcome have changed?

Conclusion

We are convinced suicidal behavior needs to be viewed as a heterogeneous concept and that we need to differentiate between various forms of suicidal behavior. Differentiation will promote introduction of alternative and innovative ways to manage suicidal behavior and professional responsibilities. It will allow research into biological, social, and psychological factors contributing to suicidal behavior being lifted to a higher level. We understand there is still a long way to go and this is a first attempt to introduce this kind of entrapment typologies.

The development of the H4ME model is a venture into unknown territory, and rather than taking the usual route of applying theoretical knowledge into practice, we took the reverse route by developing a theoretical model based on practical experience.

Development of the model involved a paradigm shift, a change in conceptual thinking about suicide, and the realization that suicidal behavior is heterogeneous and multifactorial rather than a uniform concept.

Abstract

Clinicians have long looked for **the** clue to suicide, whether depression, the perception of being a burden, deception, whatever. Different practitioners have focused on different cues, often with many suicidal people dying. It will be argued that the most important development in suicidology, since Shneidman and Farberow's 1957 original work on multidimensional clues to suicide, is the conclusion that an algorithm or formula may be more predictive than a single cue. The classical example of this approach in health is anesthesiologist Virginia Apgar's use of multiple variables in a formula to predict possible brain damage or death after infant birth. Her, now called, Apgar score saved and continues to save lives. She argued for a formula. It is suggested that similarly the use of a

A. A. Leenaars (✉)

e-mail: draalee@sympatico.ca

multidimensional approach is equally more effective in suicide prediction than any single symptom or clue. This is as true in death scene investigation (DSI), called the psychological autopsy (PA), as in the therapy room. The question, posed in this chapter, can suicidology develop an effective tool to postdict in DSI, a death as a suicide versus another mode of death (e.g., homicide, accident). This chapter will explore the question, “Should we use a cue or formula in our formulations in the PA?” An answer will be provided, based on decades of research, and illustrated by the internationally known forensic case of *The State of Indiana vs. Bei Bei Shuai*. Conclusions will be addressed.

Introduction

The concept of investigating deaths, which are uncertain (equivocal) as to the mode of death – natural, accident, suicide, or homicide (NASH) – is at least as old as the work of John Graunt of London, England in the seventeenth century. By that time, death records were being kept; however, Mr. Graunt’s genius lay in aggregating the mortality data into population estimates and constructing the first mortality tallies. Graunt was for the first time, in an accurate formula way, able to show the regularities (patterns) in the deaths and, thus, showed that mortality data had great advantage for police, physicians, and the government in assessing individual causes of death and death investigation. Yet, death scene investigations (DSI) have always been shrouded in deep veils of mystery. Thus, the purpose of this chapter is to show that it need not be that mysterious. It can, as Graunt already showed, be evidence-based. Not only Graunt but also clinical suicidologists can master it.

The recent American history of DSI on suicide focuses around the Los Angeles Suicide Prevention Centre (LASPC). In the 1950s, the Chief-Coroner and Medical Examiner of Los Angeles County, Theodore J. Curphey, asked the leaders of the LASPC – Drs. Edwin Shneidman, Norman Farberow, and Robert Litman – to assist him with coroners’ cases which were ambiguous as to the mode of death, usually between accident and suicide – although there were cases of homicide and suicide too. These were cases that depended on the decedent’s *intention*. The Centre’s three leaders were designated as deputy coroners and attended to the scenes of death, where they gently interviewed a number of key informants, and then reported back to Dr. Curphey in a consultation setting that was strictly non-partisan; that is, no one had a brief for one mode of death or another (e.g., homicide or suicide). Shneidman labeled this clinical-scientific procedure the psychological autopsy (PA), although whether you call the death scene investigation, a PA or the traditional term, DSI, is a matter of personal/ecological preference. Regardless of the name, it is a death scene investigation from a psychological/psychiatric view, just like other experts come at

the death from their view, such as the police. This chapter reflects Dr. Edwin Shneidman's – my mentor's – words and teachings. The PA can be like fingerprinting and DNA analysis; at least, Dr. Shneidman and I believe so. It allows one to see for oneself. The PA is, at this time, the best road map to uncover the intent of the suicidal mind.

Since Graunt's work, there has been a sizable percentage of deaths that were equivocal as to mode precisely because the psychological factors were unknown. Medical examiners, coroners, and police officers throughout the world can be, however, empowered when they employ the special skills of behavioral scientists (e.g., psychologists, psychiatrists) in cases of equivocal deaths. The skills of behavioral scientists should be employed in the same way as the skills of biochemists, toxicologists, microscopists, and other physical scientists. The time has long since passed when we could take advantage of the luxury of disregarding the basic teachings of the twentieth-century – and for that matter, the twenty-first-century – psychology and psychiatry. DSI procedures (and the death certificates on which the mode of death are recorded) should reflect the role of the decedent in his own demise, and in equivocal cases, this cannot be done without a PA.

As Dr. Shneidman notes:

The retrospective analysis of deaths not only serves to increase the accuracy of certification (which is in the best interests of the overall mental health concerns of the community), but also has the heuristic function of providing the serious investigator with clues that he may then use to assess lethal intent in living persons. (Leenaars [18], p. 401)

The PA allows you to do DSI, not in a mysterious way. It will empower not only the coroner or medical examiner but also police investigators and mental health professionals. In this chapter, we take a look at the question, "Should we use a cue or formula (algorithm) in our formulations in the PA?"

What is an algorithm? An algorithm is a formula. It comes from the Greek, *arithmos*, number. Algorithm is often associated with the mathematician Abu Ja'far Muḥammad ibn Mūsā (c.800–47); he is a widely translated author on arithmetic and algebra (algorism). An algorithm, according to the OED, is "a procedure or set of rules for calculation or problem solving." It is now most often associated with a computer; however, it can be done by hand, as Abu Ja'far Muḥammad ibn Mūsā taught. This is my working definition in this chapter. First, however, we have to explicate, "What is suicide?" In the main text, we will then look at the following:

- How do we study suicide?
- A model of suicide
- The psychological autopsy
- *The State of Indiana Vs. Bei Bei Shuai*
- Dr. Virginia Apgar
- The algorithm that postdicts
- Conclusion

Suicide

Suicide is violence. It is intentional self-directed violence. The World Health Organization [54] defines violence as:

The intentional use of physical force or power, threatened or actual, against oneself, another person, or against a group or community, that either results in or has a high likelihood of resulting in injury, death, psychological harm, maldevelopment or deprivation. (p. 5)

Intentionality is central. Yet, suicide is more; it is a multidimensional event [14, 17, 46, 49]. It is not simple; it is not simply depression, or being a burden, or whatever single factor. Only a complex multifactorial model helps to understand and thus predict or postdict the nature of the death [46]. Suicide is the result of an interplay of individual, relational, social, cultural, and environmental factors. The WHO [54] states that to understand suicide, we need an ecological model (see Fig. 1).

Shneidman [49] may have defined suicide best with the following heuristic definition:

Currently, in the Western world, suicide is a conscious act of self-induced annihilation, best understood as a multidimensional malaise in a needful individual who defines an issue for which suicide is perceived as the best solution. (p. 203)

What this definition means was the subject of an entire book, *Definition of suicide* [49]. *Intentionality* is central. Suicide is an intentional act [36, 37]. As Litman [36] noted:

The concept, which defines a death as suicide rather than an accident, is intention. For example, we assume that when a man shoots himself in the head with a gun, he intended to die. Therefore, the death was a suicide. However, if in fact, he intended to survive, for example, if he thought the gun was not loaded, the death was accidental. (p. 88)

Fig. 1 Ecological model for understanding suicide

Therefore, the concept, which defines a suicide, is intention. Suicidal intent can be defined as “understanding the physical nature and consequences of the act of self-destruction” [43, p. 53]. The concept of suicide requires that the self-directed violence has, for at least one of its purposes or goals, the death of the person. Litman [37] further stated:

The concept ‘intentional’ signifies to me that the individual in question understood, to some degree, his or her life situation and also understood, to some degree, the nature and quality of the self-destructive action (the proposed action representing to some degree, in the person’s mind, killing one’s self as a solution to the life situational problem). (p. 72)

Thus, the person who intends to die, by Litman’s definition, would have to understand the finality of the act. A common question, often asked by people is, “How is suicide intent determined?” The question is: “How can you reach an opinion about what was in the mind of a person who is now dead?” Of course, it would be best to ask a person what he or she intended and/or understood; yet, in all cases of suicide, we cannot. As Nolan (a lawyer) [43] stated:

Since the suicide victim is dead and unavailable for direct inquiry as to his intention, professionals charged with making such determinations have developed the standard investigatory technique now known as a psychological autopsy. (p. 56)

Litman [37] makes the further obvious point about intention even in living people. He stated:

Unfortunately, absolute certainty about human intentions is seldom achieved even with the living, including our patients, colleagues, and families. We constantly act upon our own evaluations of others’ intentions based upon their verbal communications, their behaviors, their previous track records and the social context. (p. 78)

This is the task in postdiction!

Next, we examine, “How do we study suicide?”

How Do We Study Suicide?

Many researchers from around the world have used different methods to study suicide. Shneidman and Farberow [52], Hawton and van Heeringen [9], and others have suggested the following avenues: national mortality statistics, third-party interviews (often called psychological autopsies [PA]), the study of nonfatal suicide attempts, and the analysis of documents (such as suicide notes). All of these avenues have their limitations. Mortality statistics by themselves reflect only numbers and are, at best, only a representation of the true figures. A third-party interview, such as in a PA, can only provide a point of view, which is not necessarily the suicide’s view. Nonfatal attempters may be different than fatal completers. Documents may provide only a snapshot of an event that requires a full-length movie. (But, sometimes they

provide a vignette of sufficient length so that some essential issues of the event can be reasonably inferred.) Yet, each of these methods has been shown to have benefits and to extend our understanding of suicide and suicidal behavior [9, 24]. One of these methods, suicide note analysis, has been the focus of Leenaars' studies.

Historically [52], the following methods of suicide note analyses have been used: descriptive/content, classification (such as male/female), and theoretical-conceptual. Shneidman and Farberow [52] have argued that the theoretical-conceptual approach offered the most promise. Leenaars used a theoretical-conceptual analysis, which uses a schema (construct, theory) approach, to understand the event, grounding the data in a foundation of science [2, 4, 13, 41]. The method utilized a thematic conceptual analysis of samples of suicide notes (see, e.g., [14, 17, 21]). Leenaars [14] developed his multidimensional model of suicide derived from the formulations of ten significant contributors in the suicidological history: A. Adler, L. Binswanger, S. Freud, C. G. Jung, K. A. Menninger, G. Kelly, H. A. Murray, E. S. Shneidman, H. S. Sullivan, and G. Zilboorg. In his model, utilizing an ex post facto research design [12], Leenaars isolated 100 protocol (theoretical-conceptual) sentences, 10 each from the 10 theorists, and reduced them empirically to 35 sentences (hypotheses). Twenty-three protocol sentences were found to be highly predictive (descriptive) of the content of suicide notes (i.e., one standard deviation above the mean of observations) and 17 protocol sentences significantly discriminated genuine suicide notes from simulated notes (i.e., control data), with five sentences being both predictive and discriminative [15, 22]. After a series of studies utilizing Leenaars' model, a cluster analysis (Varaclus procedure, oblique component) was undertaken [15]. The analysis produced a classification of eight discrete clusters (where an eigenvalue of 1.00 was used as the criterion). This number of clusters accounted for 56% of the variance (see Millon [41] on cluster analysis). The eight clusters, grouped heuristically into five intrapsychic (mind) and three relational aspects, were as follows: Unbearable Psychological Pain, Cognitive Constriction, Indirect Expressions and (Self)Deception, Inability to Adjust/Psychopathology, Weakened Resilience (Ego), Interpersonal Relations, Rejection-Aggression, and Identification-Egression [17, 26]. (Appendix 1 presents the 35 protocol sentences, organized in each cluster, presented in a heuristic assessment tool, the Thematic Guide to Suicide Prediction [TGSP].)

Independent research on suicide notes [42, 45], investigations of suicidal Internet writings [1], and biographical studies of suicides [34] have supported the utility of Leenaars' approach to suicide notes, or any narrative analysis (e.g., poems, Twitter posts). Independent studies of inter-judge reliability (e.g., [1, 45]) and four decades of study by Leenaars and international collaborators show that the percentage of inter-judge agreement has been satisfactory (>85%). Reliability has also been established in different countries, and we will next briefly highlight those studies.

Much of our understanding of suicide may be culture specific. Thus, caution is needed in the field. Studies from Australia [28], Canada [16], Germany [23], Hungary [25], India [29], Lithuania [31], Mexico [3], Russia [27], the United Kingdom (Northern Ireland) [44], the United States [14], and Turkey [30] showed that there were great similarities on Leenaars' variables. Thus, compared to most suicidological theories, there is a great deal of cultural applicability. It is not culture specific, say American only [19].

A question, however, arises, what about other methods of study? Can we find corroborative evidence for Leenaars' schema with other sources of data? Verification is a basic in science [2, 41]. Leenaars, Dieserud, Wenckstern, Dyregrov, Lester, and Lyke [32] corroborated the theory by way of a psychological autopsy (PA). A PA study was undertaken in Norway, with 120 survivors/informants. The sample consisted of five to nine informants for each of 20 suicide victims. Interviews, i.e., narratives and in-depth questions, based on Shneidman's procedures/protocols, were conducted (see more below). The survivors overall told stories that supported the people who died by suicide's view. Suicide victims and survivors tell the same lived experience.

A Model of Suicide

Suicide is *intrapsychic* (mind). Suicide as a solution occurs in a mind. However, suicide is not only intrapsychic, it is *relational*, often interpersonal. Metaphorically speaking, suicide is an intrapsychic drama on a relational stage. Suicide, we have learned, can be clinically and forensically understood from at least the following evidence-based commonalities or patterns, both mind (intrapsychic) and relational (often interpersonal) factors. It is a multidimensional perspective, entirely consistent with the WHO ecological view. (I have here attempted to update my terms and language to more current usage, e.g., ego strength was a common term; however, today, resilience is more used.)

Here are five main clues (evidence) of the suicidal mind that we have learned:

I) *Unbearable Psychological Pain*

The common stimulus in suicide is *unbearable* (unendurable) psychological pain [49, 50]. The enemy of life is pain. The suicidal person is in a heightened state of perturbation, an intense mental *anguish*. The author, William Styron [53], called it, "The howling tempest of the brain." Dr. Edwin Shneidman [50] called it a "psychache." Shneidman wrote: "*Suicide is caused by psychache* (sik-ak; two syllables). Psychache refers to the hurt, anguish, soreness, aching, psychological pain in the psyche, the mind. It is intrinsically psychological – the pain of excessively felt shame, or guilt, [*or depression, or anxiety*], or fear, or angst, or dread of growing old, or dying badly, or whatever." It is the pain of feeling pain, the *pain* of pain. It is especially the feeling of hopelessness-helplessness that is so painful for many suicidal people. The suicide is functional because it abolishes the pain and provides what the person perceives as "the best solution."

II) *Cognitive Constriction*

The common cognitive state in suicide is mental constriction. Constriction, i.e., rigidity in thinking, narrowing of focus, tunnel vision, concreteness, etc., is the major component of the cognitive state in suicide. The suicidal person is figuratively wearing horse blinders and is intoxicated by the blindness. Although there are more cognitive distortions (beliefs) in the suicidal mind, something is almost *always* either A or not A; there are no grays (harassment at

work or not, married or not, fit for duty or not, whatever, either, or). It is black or white thinking. (Listen for words like, “ever,” “always,” or “never.”) The constriction is one of the most dangerous aspects of the suicidal mind. It kills!

III) *Indirect Expressions and (Self)Deception*

Ambivalence is the common internal attitude to suicide. The suicidal person is at least of two or more minds. There are indirect expressions. In everyday (Aristotelian) logic, something is either A or not A; yet, in the suicidal mind, something can be *both* A and/or not A (spouse and/or no spouse, fit for duty and/or not fit for duty). We can both love and hate. Not only is it, love and hate, but it may also be a conflict between survival and unbearable pain. There are concomitant contradictory feelings, attitudes, and/or thrusts, often even toward life. Indeed, the suicidal person may be least aware of, or perplexed by the reasons *why* death is chosen (self-deception). It may be unconscious. There are likely more reasons to the suicide than the person is consciously aware of and/or communicates. Thus, it follows that we cannot often see the planned intent (clues). It may be *equivocal*. There is masking or camouflaging (keeping secrets). There are walls. Shneidman calls the masks *dissembling*. To dissemble means to conceal one's motives. It is to disguise or camouflage one's feelings, intention, or even suicide risk. In a recent published PA study, we found that over 80% of informants/survivors reported a mask [33].

IV) *Inability to Adjust/Psychopathology*

People with all types of pains, problems, psychopathology, etc., are at risk for suicide. Psychological autopsy studies suggest that 40–90% of people who kill themselves have some symptoms of psychopathology and/or problems in adjustment; whether one uses the word/concept of impairment, imbalance, problem, distress, disorder, illness, psychopathology, or the like is a matter of personal/ecological preference. Many people who died by suicide appear to suffer from mental disorders (e.g., depressive disorders, bipolar disorders [manic-depressive disorders], anxiety disorder, borderline personality). Yet, a relatively large number of cases may be most consistent with a disorder not otherwise specified. They are totally paralyzed by pain and have no reason for living. An important point: it is crucial to remember that suicidal people experience unbearable pain (psychache), not always depression (or anxiety), and even if they do experience depression, the critical stimulus is the “unbearable” nature of the depression (or some other mood). Suicidal people see themselves as in unendurable pain *and* unable to adjust (adapt).

V) *Weakened Resilience (Ego)*

Resilience (or ego strength) is defined as the capacity to adapt successfully in the presence of risk and adversity [40]. It is the ability to adjust to challenging life experiences and even suicide risk. The suicidal mind lacks resilience. The OED defines ego as “the part of the mind that reacts to reality and has a sense of individuality.” Ego strength is a protective factor against suicide. Suicidal people, however, frequently exhibit a relative weakness in their capacity to develop constructive tendencies and to overcome their personal or system adversities [55]. The suicidal person's ego has likely been

weakened by a trauma or a steady toll of traumatic life events. This implies the following fact: There is in the suicidal mind, to put it in one simple word, vulnerability. There is a lack of resilience. This weakened (do not read, weak) resilience correlates positively with suicide risk. Resilience (ego strength) is a protective factor against suicide, and building resilience allows a wounded person to prevent the final exit!

Having discussed the suicidal mind, next here are three main clues (evidence) of the suicidal relational (often relationship[s]) context that we have learned:

VI) *Interpersonal Relations*

The suicidal person has problems in establishing or maintaining attachments (with a person[s] or with another ideal[s]/relation[s], such as employment, health). Most frequently, there was/is a current and/or long-standing disturbed, unbearable interpersonal problem. It may have been a suicidal (suicidogenic) relationship. A calamity prevailed; some of the reported problems in our PA corroborative study were as follows: relational (marital) break-up, abuse in childhood, death of a parent, parental divorce, family secrets, parental conflict, bullied at school, loss of job, work-related problems, business failure, unaccepted by a person (e.g., lover, father, mother), divorce from partner, separated from lover, and more. The suicidal person has problems in establishing or maintaining relationships (object relations). The person's psychological needs were frustrated. Suicide appears to be related to an unsatisfied or frustrated attachment need (to a person and/or another relation/ideal), although other needs, often more intrapsychic, may be equally evident.

VII) *Rejection-Aggression*

Wilhelm Stekel first documented the rejection-aggression hypothesis in the famous 1910 meeting on suicide of the Psychoanalytic Society in Freud's home in Vienna [14]. Loss is central to suicide; it is, in fact, often an interpersonal rejection or abandonment, although the loss can be another relational ideal (e.g., health). It is an unbearable narcissistic (excessive self-centered, all-encompassing, overwhelming, *unbearable*) injury. This injury/traumatic event(s) leads to unimaginable pain (psychache) and in some, maybe many, masking and (self-directed) aggression. Shneidman and Farberow [52] reported that both hate directed toward others and self (self-blame) are evident in suicide [52]. Aggression is, indeed, a common emotional state in suicide.

VIII) *Identification-Egression*

Freud [8] hypothesized that intense identification with a lost or rejecting person or, as Zilboorg [55] showed, with any lost relation/ideal (e.g., health, youth, employment, and freedom) is crucial in understanding the suicidal person and especially the suicidal relationship(s). Identification is defined as an attachment (bond), based upon an important emotional tie (relation) with another person (object) or any ideal. If this emotional need is not met, the suicidal person experiences a deep pain (discomfort), deeper than thou would be aware. Deep is the crucifying *agony*. There is an intense desperation and the person wants only to egress. Suicide *is* the best solution. Suicide is *escape*.

In concluding, we have shown [19, 21] that the theory proposed is useful to not only meet the challenge on “What is Suicide?” but also to develop complex models of prediction and, thus, postdiction. It, thus, allows us to control/prevent the event.

Furthermore, in concluding, to address the question, “Why do people kill themselves?” or, more specifically, “Why did that individual die by suicide?” we need a psychology of suicide. We, fortunately, have a psychology of suicide. We have answered the question, “What are the important psychological dimensions of suicide?” – rather than, “What kind of people die by suicide?” The common consistency (“commonalities”) in suicide, among people around the world, has utility in understanding suicide and, thus, forensic investigation, prediction, and control. . .the very aims of forensic science.

Next, we briefly look at the PA as our DSI tool.

The Psychological Autopsy

Our question: What was the mode of death? Natural? Accidental? Suicide? Homicide? (NASH). An answer: Imagine we have a person, who died by falling from a tall building. The question asked is the NASH question, “what is the mode of death?”. Was it natural; did the person fall after suffering a fatal heart attack? Was it an accident; did the person slip, due to a wet environment? Was it a suicide; did he intentionally jump? Was it homicide; did someone push him off the building? How do you decide?

The psychological autopsy (PA) is the work of Edwin Shneidman [18]. The PA was devised to clarify what the mode of death was; why did the individual do it; and how did the individual die, and when – that is, why at that particular time [5, 18, 21, 38, 48, 50, 51]. A psychological autopsy is an objective procedure that seeks to make a reasonable determination of what was in the mind of the decedent vis-à-vis his or her own death. It does this by looking at the history of the decedent, the lifestyle, the intrapsychic and relational (interpersonal) characteristics, the cognitive style, the psychopathology, and so on. On the PA, Shneidman stated: “It legitimately conducts interviews (with a variety of people who knew the decedent) and examines personal documents (suicide notes, diaries, and letters) and other materials (including the autopsy and police reports) that are relevant to the psychological assessment of the dead individual’s role in the death” [18, p. 414]. Of course, a major limitation is that the story learned in a PA is the survivor’s beliefs, not the deceased’s beliefs [21], something the study of suicide notes attempted to address [52].

The psychological autopsy is primarily performed by talking to some key persons – spouse, lover, parent, grown child, friend, colleague, physician, supervisor, and coworker – who knew the decedent. This does not mean that the PA is not without controversy [10, 21, 47]. In their review paper, Pouliot and De Leo [47] emphasized several of them; e.g., most PA studies being conducted under the medical model paradigm often imply a causal link between a mental disorder and suicide; the use of nonstandardized and/or ill-defined instruments in the diagnostic process; and the use of responses from proxies, although the instruments have not been designed for this

type of use. Also, there may be problems with interviewer bias as well as lack of systematic control of number of informants and type of informants or their relationship with the deceased. Further, qualities of the interviewers and time between death and interviews vary by study. We believe that we should be especially mindful of the number of informants (witnesses) and their relationship to the deceased, whom we need to interview. No good detective, after all, would interview just one witness.

Not only may the memory of informants be unreliable, but close survivors (such as a parent) may actively be denying any role in the suicidal process [35]. For the closest relatives (e.g., parent, spouse), for example, the narratives of the survivors may be influenced by shameful feelings and, therefore, they look outside of the family to find explanations (blaming work, colleagues, lovers, spouses) [7]. This may be particularly true for parents of deceased younger people who died by suicide. Therefore, it is important to secure information from many informants and to include informants who position themselves in different ways to the deceased. This may be crucial in getting the kind of information we need to be able to better understand significant reasons behind suicides. Our conceptualization of suicide may be highly enriched by interviewing several informants around each case; often, this is called alternative constructions.

What was the mode of death? The answer is often easy in unequivocal cases. The *equivocal* (uncertain) case is, however, often perplexing. Yet, it does not have to be mysterious. The concept of investigating deaths that are uncertain as to the mode of death – NASH – is as old as the work of John Graunt. The PA is generally considered today to the best procedure/method to answer the question of mode, as well as why [5, 21, 38, 47, 48].

The question, posed next in this chapter, can suicidology develop an effective tool to postdict effectively and credibly in DSI, a death as a suicide to another mode of death, the NASH question. We will explore the question, “Should we use a cue or algorithm in our formulations in the PA?” An answer will be provided, based on decades of research, and illustrated by the internationally known forensic case of *The State of Indiana vs. Bei Bei Shuai*.

The State of Indiana vs. Bei Bei Shuai

Bei Bei Shuai was born on September 6, 1976, in Shanghai, China; she got married, and, with her husband, emigrated to the United States in 2000. Unfortunately, her marriage ended in 2008; she struggled economically. Bei Bei subsequently developed a relationship with an older married man (Zhiliang Quan; his name is a matter of public record), who promised to divorce and marry her. After an 18-month relationship, she became pregnant. She experienced severe depression during the pregnancy; she had three documented episodes of suicidal ideation and attempts. There was intimate partner dissembling and abuse. Mr. Quan abandoned her in the end, leaving Bei Bei Shuai on her hands and knees, clearly emotional, in a parking lot, throwing money at her as he drove off. He told her he did not want her or the baby.

Bei Bei Shuai had suffered from depression; she became very distraught, felt abandoned, was deeply shamed, and was suicidal. In China, there is great shame for being pregnant and unmarried. She wrote the following (translated) suicide note:

How could I be abandoned this way and not feel any sorrow? Am I supposed to pretend?	(First Page) Zhiliang Guan. Why is a man's mind so cruel, so unfeeling? Ah! At the moment when you threw money and turned away, it made me so sad and desperate. Why does the man who used to be intimate with me now try to stay away from me like I'm a snake or a scorpion? Throw all love and justice. <i>(This is a Chinese proverb that Describes someone who forgets about love and loyalty to each other in the past)</i>. I am just a dirty rag that you can't wait to get rid of. You even see my sorrow and tears as an act to earn sympathy. Zhiliang Guan, what kind of person you are! Your words are like a knife piercing deeply into my heart. This makes my wounded soul even more painful – and my heart and lungs are in deep sorrow. At the very moment my heart broke into pieces. Zhiliang Guan, have you really forgotten me – a person of flesh and blood with feelings? A woman who is about to give birth to a baby! Zhiliang Guan, I have been working hard with my two hands in this foreign land of America for over ten years. I have been very passionate about helping and caring for everyone around me. I've never given into the temptation to take another person's belongings. I really don't understand why I have become such a bad woman in your family's eyes. (Second Page) I have poured out all the love and caring for you that a woman can give. I always think of you first. I've given you the best and loved you with all my heart. Why would your family see me as a woman with vicious intentions? Why would your family talk about me as if I were a skittish, bad woman? Zhiliang Guan, right now I know that my existence as well as the child's is a burden, trouble and even a hindrance to your own happy life. So I choose death to give you a successful and happy life in the future. I am only asking you to have DNA tested or find a parent/child association after my death. Please prove my innocence to your family and show them that half of baby Crystal's genes are your own, Zhiliang Guan. I am taking this baby, the one you named Crystal, with me. There is no need to find my friends. Why bother? On the way to Hades (death), I will take care of her. Please leave me with a bit of personal dignity after my death

On December 23, 2010, Ms. Shuai attempted suicide by consuming rat poison, a common method in China. She did not die. She was hospitalized, as well as diagnosed with and treated for major depression. She was assessed to be at risk for suicide. Bei Bei Shuai survived her attempt; however, complications occurred with her child (fetal). On December 31, 2010, her baby was delivered by cesarean surgery, but 10 days after the attempt, her daughter, Angel, died on January 3, 2011. Detectives began an investigation and Bei Bei Shuai was arrested on May 14, 2011. She was taken into custody in the high-security Marion County prison. She was charged with murder and feticide. She was in jail for 435 days and faced a sentence of 45 years to life.

There was a law in Indiana, enacted in 1979, to protect pregnant women from violence by their partner, such as abusive husbands. Shuai's case was the first in the history of Indiana in which a woman was prosecuted for murder for attempting suicide while pregnant. The American Civil Liberties Union, National Advocate for Pregnant Women, and health groups like the American Association of Suicidology, and the American Medical Association, came to Ms. Shuai's aid. Indeed, international press coverage and support arose for Bei Bei and all pregnant women who may be suffering from mental illness and suicide risk. Of course, it would be obvious that if Shuai was convicted of murder, women would be discouraged from getting help. Pregnant women would be branded; that is *stigma*! However, despite the national and international protest, the prosecuting team persisted with the murder charge. Among other independent professionals, I was retained by Pence Hensel, LLC, to provide expert consulting service for Bei Bei Shuai. I was to be a suicide expert at trial. I provided a deposition, on June 27, 2013; I will present some verbatim testimony below. I was set to testify at trial in September. However, after the depositions, the charges of murder and feticide were dropped; her lawyer believed that I was one of the reasons ("You were wonderful!").

The Evidence

From a systematic review, we know that studies have reported low suicide rates during pregnancy; depression is often associated [21]. The low risk is, however, for suicide; pregnant women are at high risk for suicide attempts and suicide ideation [21]. There was abundant evidence that Bei Bei Shuai was, at the time of her attempt (and before), at a high level of lethality and perturbation. She was depressed and highly suicidal; her mind was a suicidal mind. Her relations were dysfunctional, especially interpersonal. She had little resilience. One could use her case as a prototype for discussions on suicide [21]. The purpose here is not to detail the idiographic assessment and facts. On *the* issue in this chapter, there was no question in my mind that she was suicidal and was suicidal at the time she wrote her "genuine" suicide note. If she had died, the mode of death was "suicide." We also have a good idea, why, and why at that particular time. As I always do, I scored her note with the TGSP (see [Appendix 1](#)) before I looked at

any other data. Bei Bei's note had the following characteristics of suicide: 1, 2, 3, 4, 5, 6, 7, 8, 9, 11, 12, 13, 14, 15f, 16, 17, 19, 20, 21, 22, 23, 25, 26, 27, 28, 29, 31, 32, 33, 34, and 35. (That is a near "perfect" suicide note.) The assessment tool, TGSP, has met legal admissibility criteria in American courts [21], and I have been accepted in courts as an expert on suicide and suicide notes. There is no question in my mind that Bei Bei's note had abundant characteristics of suicide. Of course, one always places the note or any evidence within the larger context of the case: all of the evidence. One never makes an opinion on an alleged suicide note alone! Next, I present some abbreviated testimony.

My Testimony

On June 27, 2013, I provided a deposition. Bei Bei's defense was headed by Linda Pence (she had no questions); the prosecutor was Courtney Curtis. I present verbatim (with some editing of oral text to written) my testimony that pertains to the issues posed in this paper. The full text can be found in Leenaars [21]. For the reader, I have inserted a few remarks in *[insert]*. (I have also placed in **bold** my words, when there was a clear increase in intensity in my voice.) I present the text:

Courtney Curtis: I'm going to assume that you have reviewed the suicide note in this case.

Al: Yes.

Al: ...There's no question that at the time of writing, this person had suicide on her mind...

... what I did with Bei Bei Shuai's note. I looked at this note; I read it a number of times. I did not look at any other information or anything before; that is my practice forensically. And then I scored her note... *[I discussed in detail the history, theory, research, peer-reviewed and independent-author(s) publications on the clusters and 35 factors/protocol sentences, reliability/validity, gender, cultural aspects and validation, etc. – see Leenaars [21]]*

... What I find is almost all these 35 factors tend to be evident in her note. There are some that are not, but the majority of the factors that I would expect were in her note. So there's no question in my mind that at that point, when that person wrote it, there was suicidal **intent**. And I can get into the specific things if you like, but you know, it depends on what you want...

Curtis: Well you know I don't think that we're contesting that it's a suicide note. I was just curious as far as your review of it... Are there, maybe, just a couple of things that stood out for you that struck you as particularly genuine?

Al: I'm concerned about the domestic violence; the bullying that occurred to this woman at the time that she wrote the note. I think she was quite sad and desperate. I think, she didn't understand how he *[Zhiliang Quan]* could throw away all love and justice, like being a rag. What also struck me was that she felt like a knife was pierced into her heart deeply. She felt wounded and in **pain**. There was a deep sorrow. She was in the pain of pain; the howling tempest of her brain was there, I think... I think, she sees herself as a good person, that she's worked hard in this country as an immigrant, like many immigrants do; and she doesn't understand why suddenly his family would call her a bad woman and this and that. I think, therefore, she ends up killing herself. The motivation is because of the proximal cause. If you will, it's sort of 'but, for the last straw', the camel's back would not have been broken. But,

for what the man said to her and what he did, throwing the money at her and leaving her there in the parking lot, I don't think this would have happened. I think he, although suicide is multi-determined, was the proximal cause of her suicide attempt. What also struck me was that she felt she was a burden. Thomas Joiner... has a whole theory that being a burden is absolutely one of the major reasons why people killed themselves. Terry Maltsberger, a Harvard psychiatrist, would call it suicidal worthlessness. I was struck that she saw herself as ... a trouble and even a hindrance to his life. I think that's why, in a mentally constricted mind, she decided to kill herself; so that, she would not be ... a trouble. And, of course, in the Chinese culture, there are all sorts of things about unmarried women and being pregnant. I think, she must have agonized over his accusation that the baby may not even be his child. I think the straw that broke her back was him. I think, if it was not but for him, this would have never occurred...

Curtis: Alright, thank you. When you say that her partner, the baby's father, was the proximal cause of her suicide, do you mean their relationship or do you mean his activities on that last day before her suicide attempt?

Al: ... I believe it's the relationship over time which was both something she wanted and was *[something she found]* confusing. But, I think, what really traumatized her was that last event. I don't think she was expecting it, when they're in that parking lot; I believe this because I've read his deposition. I specifically asked for that deposition from Linda ... And so, there's no question in my mind from my clinical point of view. You know, if it was a psychologist, doing that *[being liable]*, he would lose his licence; he may be criminally charged...

Curtis: Okay. And then, you looked at other pieces of evidence or other documents to do what?

Al: Well the main thing I wanted to know was whether this was actually a suicide. People believe there was a suicide attempt, at least from the facts. The information that I've gotten, there seems to be an acceptance that this was a real suicide. I've been involved in cases where there's a note, but no suicide. Some people write a note and then they decide not to kill themselves and they put the note away. In terms of being suicidal, for suicidal-at-risk people, it comes and goes... Therefore, the important thing for me was that it was *[a genuine suicide]*, and I wanted to know a little bit about what occurred specifically in the event; so, I got the deposition...

I mean, I would love to do a complete psychological autopsy in this case. I would love to interview the people involved, Quan, etc., the police, the doctors, but that is not my responsibility. That's yours in this case.

Curtis: ... So, when you reviewed Ms. Shuai's note, it makes no difference that she survived; what you're looking for is her suicidal intention.

Al: That's correct.

Curtis: Can you review a suicide note and determine if someone has a mental disorder from its content?

Al: You know, I can make some inferences, but I would never make a diagnosis simply from the note in terms of, that a person has a mental disorder from simply a note, or from a poem, or from whatever. You'd want, as a clinician, to have much more. Now, for research purposes, you might want to do that. This is where having more information about Bei Bei Shuai would be helpful to me in terms of understanding her; but, my belief is that she was suicidal. But, I would never say, because I'm clinically allowed in this province *[Ontario]* to make a diagnosis, I would never say she clearly has a mental disorder; she clearly has a depressive disorder...

Curtis: Ok, since we can't make a diagnosis of a mental disorder, we are just speaking about suicide or, I guess, someone who is suicidal in this instance. Correct?

Al: Yes, but, you know, I believe she was ... depressed, but I would want more information to say she could have been diagnosed *[with a mental disorder]*. I don't want to do any kind of jumping to conclusions from a factor that I see, and then, the clinical or

legal thing of making a diagnosis. I would want much more information. I would want the doctor's notes. I would want to speak to the doctor; I would want whatever information is available. . . . to know whether there is a mental disorder, you need more information. . .

Curtis: Do you have enough information in this case to make a similar determination?

Al: All I can say is that based on the note, I think, she was extremely mentally constricted and I think she was overwhelmed, traumatized; she felt to be a burden. I can make those kinds of statements. But, I can't determine whether she's sane or insane from that note. I mean that's a much larger question. But, it's quite clear that she was mentally constricted, in my mind. I mean, I make those kinds of inferences in terms of **intention** every day in my office. I (We) make inferences about what people plan and intend, based on what they say in my office, people's behaviors, what they write and maybe even the books that they ask me about or what they say is their favorite book. . .

Curtis: Have you prepared or are you prepared to speak about the criminalization of suicide?

Al: Yes, if asked.

Curtis: What would you say?

Al: I have presented to my [*Canadian*] parliament, a parliamentary committee; stigmatization and criminalization were clearly part of that report. I think, it would be a horrible mistake [*to criminalize suicide*] because if you criminalize a small group of people for being suicidal, history shows that you are going to get a lot of people not getting help. If I'm depressed and pregnant and think I might get arrested, I'm not going to go to a doctor. Most of us in the field, and including in associations, the American Association of Suicidology, of which I've been a President, the only non-American, would fight this, would be opposed to this. This would result in many more people not getting help. It's like, in the military, people that were suicidal were put in jail. In police services, if I'm a police officer and I'm depressed, I will lose my gun and my badge. So, we know from studies and from the history that criminalization of depression, being suicidal will result in less people seeking help. . .

. . . The problem is that people, who were suicidal, used to be seen as, especially women, as witches. They were burned and thrown into the water. I don't want to get back to that kind of thing, where we're going to see pregnant women, because of a natural hormonal, and complications, like witches. And, that we go on a witch hunt, towards women who are pregnant and suicidal. We need to get rid of the stigma. Stigma is one of the major killers and not only stigma by the general population but, you know, by people in my profession. . .

Therefore

Therefore: I think that we can be reliable, credible, and . . . Yet, you may ask, "How did you make the forensic decisions? Did you use one clue? Or a formula?" I will next attempt to illuminate our method, using Bei Bei's suicide note. I do this only to be simple in my illustration, a full PA case study/analysis can be found in Leenaars [21]. Of course, in our real life PAs, suicide notes can have a great deal of meaning, if they are put within the context of the trove of details of the deceased's life [49]. To put it plainly: we need all of the evidence, not one datum. I have been involved in multiple forensic cases, for example, where there is a "simulated" suicide note, but no suicide [21]. In general, furthermore, I want to be cautious in giving an *absolute* outline, but inasmuch as methods have been requested now and then, I will present *a* formula below with caution to investigators to be always mindful of the ecological fallacy; i.e., going from the nomothetic (general) to the idiographic (single/individual). For example, you may hear the sound of hooves outside your window, assume

it is a horse, but it is a zebra, and rarely may be an elephant. Thus, how do we best determine the mode of death in a PA? Before I answer our pivotal question, however, we first must digress to a discussion of Dr. Virginia Apgar.

Dr. Virginia Apgar and Formula

Many researchers believe that formulas are better than single cues [11, 39]. This is especially true when predictability is poor as is the case in equivocal death scene investigation (DSI). Meehl [39] suggested “to maximize predictive accuracy, final decisions should be left to formulas, especially in low-validity environments” [11, p. 225]. Usually, one cue in our cases results in numerous errors; we need to be multidimensional. Suicide *is*. Therefore, we cannot use one factor; yet, how do we translate multidimensional into a simple *Carnapian* equation? The formula should not be too complex. (One is not a computer.) In fact, equal-weighting schemes are best; for example, one should *not* put the highest value on one cue, most often in our field, for example, depression. Rather, “formulas that assign equal weights to all the predictors are often superior, because they are not affected by accidents in sampling” [11, p. 226]. You do not have to be a computer; in fact, in court, such information is not readily understood.

From his meta-review, Kahneman [11] concluded, “it is possible to develop useful algorithms without any prior statistical research. Simple equally weighted formulas based on existing statistics or on common sense are often very good predictors of significant outcomes” (p. 226). Despite a few calls for *only* computer prediction in suicidology, I believe that you do not need to be a computer. In fact, we should not use such complex statistical equations in our DSI. Simple formulas are best, but they are formulas nonetheless. Working from Meehl’s studies, Dawes [6] had, in fact, clearly shown that simple, constant formulas are statistically significantly better than complex computer models (e.g., multiple-regression models). Maybe, all you need is your trove of evidence and a piece of paper to calculate your algorithm.

Probably the best-known classical example of the wisdom of simple formulas is the work of Dr. Virginia Apgar. Dr. Apgar was an American obstetrical anesthesiologist in the twentieth century. Dr. Apgar, among many other achievements, was the first female full professor at Columbia University College of Physicians and Surgeons.

Infant mortality has throughout the ages been a concern. From the 1930s to the 1950s, at least in the United States, infant mortality rates had decreased and remained constant. Virginia Apgar, like Abu Ja’far Muḥammad ibn Mūsā and John Graunt in their respective fields, noticed a trend and began investigation of lowering (preventing) infant mortality within the first hours of birth. She asked, “How can we distinguish healthy infants from infants at risk?” What do we look at?

Obstetricians knew at the time that a newborn not breathing normally within a few moments after birth is at risk of brain damage and/or death. Standard practice at that time was that physicians used single cues to assess a baby’s distress. Different physicians used different clues. Some would monitor the breathing; they believed it was the best clue. Others focused on color; still others whether the baby cried. They *all* believed that

they had discovered what predicted mortality best (as we see in our field of suicidology today). There was an enormous list of *the* factor; every expert espoused his or her belief. Yet, no single efforts decreased the risk. Why? Likely, as Apgar wisely concluded, without a standardized formula, danger signs were missed, and many infants died.

Dr. Apgar's genius lay in her belief that assessment must be multidimensional. No single cue would predict accurately and validly, she believed. Thus, she designed the first standardized formula or algorithm to evaluate the newborn's transition to life outside of the womb. From her investigations, that met enormous resistance from the so-called experts (as, again, no different in our field today), she isolated five main clues (evidence) of infant mortality risk: heart rate, respiratory effort, muscle tone, reflex response, and color. Each of the five factors are observed and given 0, 1, or 2. A score of 0 meant being in distress. A score of 2 meant a newborn is in an optimal condition. A 1, thus, was a midpoint. The points are totaled to arrive at a baby's overall score, the Apgar score. The scores were compiled for each newborn and can range from 0 to 10, with 10 being the "perfect" score. These babies always survived (although, of course, Meehl's familiar "broken-leg rule" applied – there are always unexpected very rare events; for a magnified example, the hospital gets bombed). The score was assigned 1 min after birth; an additional evaluation, as needed, could be given in 5-min increments. They would help to guide the intervention over a short time. It is simple. No computer was used by Apgar; just a simple algorithm was calculated. Dr. Apgar was able, in fact, to show in a formula how to predict an uncertain event effectively. Furthermore, it was easy to show inter-judge reliability and predictability. Every physician can learn the method.

It would be a truism that Apgar's algorithm, the Apgar score, saved millions of lives. That is huge in prediction!

A story as told by Daniel Kahneman [11]:

One day over breakfast, a medical resident asked how Dr. Apgar would make a systematic assessment of a newborn. "That's easy," she replied. "You would do it like this." Apgar jotted down five variables (heart rate, respiration, reflex, muscle tone, and color) and three scores (0, 1, or 2, depending on the robustness of each sign). Realizing that she might have made a breakthrough that any delivery room could implement, Apgar began rating infants by this rule one minute after they were born. A baby with a total score of 8 or above was likely to be pink, squirming, crying, grimacing, with a pulse of 100 or more – in good shape. A baby with score of 4 or below was probably bluish, flaccid, passive, with a slow or weak pulse – in need of immediate intervention. Applying Apgar's score, the staff in delivery rooms finally had consistent standards for determining which babies were in trouble, and the formula is credited for an important contribution to reducing infant mortality. The Apgar test is still used every day in every delivery room. (p. 227)

Can we do the same in postdiction in our PAs? Of course, this is the same question; as the following, can we predict suicide risk in our therapy rooms? What we already know is that Dr. Apgar went on to the next step, applicability and intervention. Because she was able to predict infant mortality accurately, Dr. Apgar went on next to prevent birth defects. She became the iconic person in the March of Dimes. Can we do the same?

The Algorithm That Postdicts

Following Meehl and Dawes' advice, I will keep it simple. Here is the equation. Like Apgar, we use a scale of 0, 1, and 2, depending on the robustness of each sign. As is obvious, the clusters are not equal in items; yet, each cluster has equal weight. A score of 2 is equal to 2/3 of the protocol sentences (PS) in the cluster and above (an overall score of 11 and above in the equation [above 10]); it suggests a *high* score on the suicide (suicidality) determination. A score of 1 is equal to 1/3 and above, to 2/3 (an overall score of above 6 [=7] to 11 in the equation); it would be a *moderate* score. A score of 6 and below would suggest *low* determination of suicide in our NASH question (it would be a score of 0). A perfect score is 16. It is assumed that we want to have a score of 11 or above to probably say "Yes." If 7 or above, but below 11, like Apgar's moderate score, we need more information, evaluations, time, etc., to answer about a definite mode of death determination. (Of course, even if one gets a low score on a note, we look elsewhere in our PA before our final NASH determination.) The scores were presented earlier and the reader can associate the numbers to the text in [Appendix 1](#). We assign equal weights; however, there is *the mind rule* as suicide occurs in the mind. Suicide is about *intentionality*. Thus, the rule: Intrapsychic beats out relational. No suicidal mind, no suicide! Here are my scores jotted down on eight variables (with name, actual protocol sentences (PS) observed, number of verified PSs out of number of PSs in cluster, and formula): (I) *Unbearable Psychological Pain*: Protocol sentences (PS) = 1, 2, 3, 4, 5, 6; 6 out of 6 PS. Formula = 2. (II) *Cognitive Constriction*: PS = 7, 8, 9; 3 out of 3. Formula = 2. (III) *Indirect Expressions and (Self)Deception*: PS = 11, 12; 2 out of 3. Formula = 2. (IV) *Inability to Adjust/Psychopathology*: PS = 13, 14, 15f; 3 out of 3. Formula = 2. (V) *Weakened Resilience*: PS = 16, 17; 2 out of 3. Formula = 2. (VI) *Interpersonal Relations*: PS = 19, 20, 21, 22, 23; 5 out of 5. Formula = 2. (VII) *Rejection/Aggression*: PS = 25, 26, 27, 28, 29, 31, 32; 7 out of 8. Formula = 2. (VIII) *Identification/Egression*: PS = 33, 34, 35; 3 out of 3. Formula = 2. Therefore, 16 out of 16, a perfect formula score. The algorithm allows us to conclude that the suicide note is genuine and Bei Bei, in my opinion, was suicidal!

Suicide occurred in her mind (the mind-rule), and she was in a suicidogenic relationship. Can one see how the formula is calculated? It will make DSI unmysterious. We can postdict suicide. Would Paul Meehl agree? I think so, so would Virginia Apgar, Abu Ja'far Muḥammad ibn Mūsā, and John Graunt.

Allow me to illustrate further, however. I will use Bei Bei's case vs. the case of Scott Dell: Scott Dell died on December 29, 1995. Since the details of this case can be found in my book, *The Psychological Autopsy* (2017), I will here only present the note found at Scott's death scene. Of course, as is obvious to any good forensic investigator, one should place the note in the context of all forensic data in the case [5, 21, 38, 48].

The cause of death was listed as "Undetermined"; yet, there were questions, was it suicide or homicide? The note, found at the scene, was called a "suicide note." The coroner and police officer, for example, had called the note a "suicide note." The note read as follows:

Dear Mr. Fantasy

Carmelita – Linda Ronstadt – Debbie Quinn

Fun – life would go on forever. Death – suicide

The truth is simple but seldom ever seen.

If Truth is Purity can it ever exist in such an impure world. If it can't what does that mean.

Are we all living in the shadows of

I feel like holding you close to me like never before I feel like making love to you I feel like all the bad stuff would go away.

You and I are stuck because of all the bad stuff that has happened to us last 3 years. We need to make it go away.

I'm trying not to think about things I want to think about. I don't know if that is what I should do or not. I can't help it. I Don't want to want you. I don't want to be rejected

If we don't get back together we maybe shouldn't see each other very much.

I thought maybe this wasn't a good night because I was too tired but I think the truth is revealed no matter what.

Sun – before

Lying on a beach with you

We forget all time that our life is a gift that has been given us to enjoy not to waste.

I doesn't last long. It is not a sin to be happy but it may be to be unhappy.

What did you think was going to happen if I drank a bottle wine listening to music we used to listen too

I'm going to think about you and me together

Maybe that's the only way you can except to thru a spiritual vision.

I seems true that is not a sin to be happy so maybe that means that it is to be unhappy

You will have to listen to your heart not your head.

I had a vision of you very briefly you were like some neophyte Angel floating in the air but you were disconnected you head from your body.

1) Mary Akroyd.

2) I was probably supposed to die

But my life was spared

I don't know why. That bothers me.

3) Let go theres nothing that you are holding onto now is going to help you

4) Let go. You are holding on tight.

5) Our lives are going by really fast

Like Bei Bei's case, this case presented a unique opportunity to postdict a communication as representing a suicide determination or not. The TGSP was used. In performing my analysis, I first looked at and scored the note before any background information was known, before a full PA was undertaken. The specific protocols scored in the TGSP are as follows: 3, 7, 10, 15g, 16, 19, 20, 21, 23, 25, 27, 28, and 35. The analysis is as follows.

The note has the following intrapsychic characteristics: (I) *Unbearable Psychological Pain*. PS = 3; 1 out of 6 protocol sentences, PS. Formula = 0. (II) *Cognitive Constriction*. PS = 7; 1 out of 3. Formula = 1. (III) *Indirect Expressions and (Self) Deception*. PS = 10; 1 out of 3. Formula = 1. (IV) *Inability to Adjust/Psychopathology*. PS = 15g; 1 out of 3. Formula = 1. (V) *Weakened Resilience (Ego)*. PS = 16; 1 out of 3. Formula = 1. Therefore, a score of 4 out of 10 in the data means *not* suicidal mind. It is a *low* algorithm score. Apgar would agree, I think; a 4 is a dangerous score on her Apgar score. Furthermore, remember the rule, mind beats relational. (Like Apgar, a score of 8 out of 10 is a "good" predictor of suicide risk.) The note has the following relational cues: (VI) *Interpersonal Relations*. PS = 19,

20, 21; 3 out of 6. Formula = 1. (VII) *Rejection-Aggression*. PS = 25, 27, 28; 3 out of 8. Formula = 0. (VIII) *Identification-Egression*. PS = 35; 1 out of 3. Formula = 1. The formula gives us a score of 6 out of 16.

Based on my training, experience, research, and that includes the use of an algorithm for decision-making, I reached the following primary opinions: there is no doubt in my mind that this is *not* a suicide note. Although low scores require a margin of error, I do not believe Scott Dell's alleged note was a suicide note. In fact, as it unfolded in court, Scott's ex-wife, Cherylle, dictated the note. She obviously did not know what a suicidal mind is. It was a fake note. Although one can read the complete text of my testimony in court [21], it may be of interest for the reader that Cherylle Dell was found guilty of murder and is now in prison. This is all very different from the case of Bei Bei Shuai. I hope that it helps to show the practical utility of a simple formula: algorithms rule. However, this should not be read as negating clinical/forensic judgment. Any good forensic investigator knows the importance of judgment, such as what open-ended questions to ask in Shneidman's PA outline or what evidence is still needed [21, 48].

Conclusion

Of course, we need more research on the work and the use of algorithms in PA postdiction. Albeit, that is a truism in all of science. We really can make important decisions *now* in postdiction of mode of death. Our formulas work; the main research need, I think, is study that focuses on admissibility of the PA in court [21, 36]. Of course, there may be other important variables, such as Maltsberger's concept of worthlessness, that may help. Yet, I wonder if it is actually needed. Like Apgar decided, I think that we have enough cross-culturally verified evidence-based variables for our algorithm. It works. Most important is to remember the rule: Simple formulas work better than complex ones.

No matter how much of a genius the expert may be, formulas work better than clinical judgment (intuition) in decision-making in multifarious equivocal NASH cases. We need to be evidence-based. We might see this or that aspect of our evidence as figural, say depression; however, that one cue does nothing in postdiction. The number of false positives would be huge. It will lead us astray. Color of a baby alone at birth did not help Apgar either in her predictions; she argued for an algorithm of five variables. Color was only helpful in the equation, not by itself. In the PA, the algorithm is best. Depression is no more important than any of the other protocol sentence in the eight clusters/characteristics. All variables are equal. Leenaars' model works because it follows the general research finding of Apgar, Meehl, and many others that formulas work better than one cue.

Despite Apgar, Meehl, Abu Ja'far Muḥammad ibn Mūsā, Graunt, and my opinion on the value of only one cue in decision-making and judgment, expert suicidologists are not only important but also necessary. Our formulas do not choose the multiple cues; Apgar chose the five variables. Leenaars chose his variables from ten leading suicidologists, followed by decades of research. It is always a person (judge, psychiatrist/psychologist, survivor) who chooses the variables [6, 21, 39]. Our

simple models “cannot replace the expert in deciding such things as ‘what to look for,’ but it is precisely this knowledge of what to look for in reaching the decision that is the expertise people have” [6, p. 573]. No computer or our simple models can do that. Apgar’s wisdom was not only in using a multidimensional formula but also in her ability to understand and choose what to look for in newborn babies. She had superb clinical judgment. Despite my obvious bias throughout this paper, we have isolated enough variables to look for to assess suicide risk. I write enough because there may be other helpful factors; yet, they may not necessarily be needed now. Maybe adding being a burden would help a little, probably not (although Niveau et al. [42] suggested it is associated to inability to adjust cluster). Depression is, of course, in the equation but as only one protocol sentence in one of eight clusters. It helps in the equation. Leenaars’ equation is sufficient. Does that mean we can stop all research? No! Science, by definition, is always a process, not an endgame.

The answer to the question posed in this chapter: *The algorithm is best!* No matter how distasteful formulas may be vs. your intuition/judgment, formulas work better. No matter how uncomfortable you are at reducing people to numbers, it works best in the PA and in court (and the therapy room). (Shneidman disagreed, largely because he did not have a mathematical mind [18, 20].) We need to do the best that we can in DSI, and that means we must use an algorithm/formula, but keep it simple. We can be as successful in our equivocal cases, as Apgar was in the delivery room. To use only one cue, say deception, we will be faulty in our NASH decisions, what the mode of death was, why the individual did it, and how the individual died, and when. Our cases deserve the best. Behavioral scientists can be as helpful as DNA scientists or fingerprint experts. Suicidologists need algorithms, but not equations that only computers can compute. It helps in nomothetic research, but not in our forensic case studies “on the ground.” *Therefore*, that important word in the OED, we must use an algorithm.

Appendix 1 Thematic Guide for Suicide Prediction

THEMATIC GUIDE FOR SUICIDE PREDICTION*

Antoon A. Leenaars, Ph.D., C.Psych.

I PATIENT DATA

Date:

Name	Age	Sex

Date of Birth _____ Marital Status _____ Divorced _____

Education Status

(years)

(degrees)

Current Employment

II SUICIDAL EXPERIENCE

- 1) Has the patient ever seriously contemplated suicide? (If yes, note particulars)

- 2) Has the patient ever attempted suicide? (If yes, note particulars)

- 3) Does the patient know anyone who attempted suicide? (If yes, indicate family, acquaintance, etc.)

- 4) Does the patient know anyone who died by suicide? (If yes, indicate family, acquaintance, etc.)

III REFERRAL DATA

- 1) Purpose _____ Postvention _____
- 2) What is the referral question? _____ See file _____
- 3) What is the presenting problem(s)? _____ See file _____

*Note: There are different cues; the letter P refers to a specific highly predictive variable, whereas the letter D refers to a specific differentiating variable of the suicidal mind. Some factors/cues can be both in your algorithm for prediction.

Copyright © 1998 by Antoon A. Leenaars. Revised 2019

IV **INTERVIEW SITUATION**

- 1) Observations _____

- 2) Other procedures (e.g., tests, interviews) _____

V **INTERPRETATIONS**

1)	Perturbation rating:	Low	Medium	High
	scale equivalent	1 2 3	4 5 6	7 8 9
2)	Lethality rating:	Low	Medium	High
	scale equivalent	1 2 3	4 5 6	7 8 9
- 3) Guide summary:
- scores: I - 1, 2, 3, 4, 5, 6; II - 7, 8, 9; III - 10, 11, 12;
- IV - 13, 14, 15; V - 16, 17, 18; VI - 19, 20, 21, 22, 23, 24
- VII - 25, 26, 27, 28, 29, 30, 31, 32; VIII - 33, 34, 35

Conclusions (e.g., formula/algorithm): _____

VI **REMARKS**

Include on back any other relevant data.

INSTRUCTIONS

Your task will be to verify whether the statements provided below correspond or compare to the contents of the person’s protocols (e.g., interview, written reports). The statements provided below are a classification of the possible content. You are to determine whether the contents in the person’s protocols are a particular or specific instance of the classification or not. Your comparison should be observable; however, the classification may be more abstract than the specific instances. Thus, you will have to make judgments about whether particular contents of a protocol are included in a given classification or not. Your task is to conclude, yes or no.

INTRAPSYCHIC Circle One

I - Unbearable Psychological Pain

1) Suicide has adjustive value and is functional because it stops painful tension and provides relief from intolerable psychological pain. (P)	Yes	No
2) In suicide, the psychological and/or environmental traumas among many other factors may include: incurable disease, threat of senility, fear of becoming hopelessly dependent, feelings of inadequacy, humiliation. Although the solution of suicide is not caused by one thing, or motive, suicide is a flight from these specters. (P & D)	Yes	No
3) In the suicidal drama, certain emotional states are present, including, for example, pitiful forlornness, emotional deprivation, distress, and/or grief. (P & D)	Yes	No
4) The suicidal person (S) appears to have arrived at the end of an interest to endure and sees suicide as a solution for some urgent problem(s), and/or injustices of life. (P)	Yes	No
5) There is a conflict between life's demands for adaptation and the S's inability or unwillingness to meet the challenge. (P)	Yes	No
6) S is in a state of heightened disturbance (perturbation) and feels boxed in, harassed, especially hopeless and helpless. (P)	Yes	No

II - Cognitive Constriction

- 7) S reports a history of trauma (e.g., poor health, rejection by

	significant other, a competitive spouse). (P & D)	Yes	No
8)	Figuratively speaking, S appears to be "intoxicated" by overpowering emotions. Concomitantly, there is a constricted logic and perception. (D)	Yes	No
9)	There is poverty of thought, exhibited by focusing only on permutations and combinations of grief and grief-provoking topics. (D)	Yes	No
<i>III - Indirect Expressions and (Self)Deception</i>			
10)	S reports ambivalence; e.g., complications, concomitant contradictory feelings, attitudes and/or thrusts. (P & D)	Yes	No
11)	S's aggression has been turned inwards; for example, humility, submission and devotion, subordination, flagellation, masochism, are evident. (P)	Yes	No
12)	Unconscious dynamics can be concluded. There are likely more reasons to the suicide than the person is consciously aware and/or reports. (D)	Yes	No
<i>IV - Inability to Adjust/Psychopathology</i>			
13)	S considers him/herself too weak to overcome personal difficulties and, therefore, rejects everything, wanting to escape painful life events. (P)	Yes	No
14)	Although S passionately argues that there is no justification for living on, S's state of mind is incompatible with an accurate assessment/perception of what is going on. (P)	Yes	No
15)	S exhibits a serious disorder in adjustment. (P)	Yes	No
a)	S's reports are consistent with a manic-depressive disorder such as the down-phase; e.g., all-embracing negative statements, severe mood disturbances causing marked impairment.	Yes	No
b)	S's reports are consistent with schizophrenia; e.g., delusional thought, paranoid ideation.	Yes	No
c)	S's reports are consistent with anxiety disorder (such as		

	obsessive-compulsive, posttraumatic stress); e.g., feeling of losing control; recurrent and persistent thoughts, impulses or images.	Yes	No
d)	S's reports are consistent with antisocial personality (or conduct) disorder; e.g., deceitfulness, conning others.	Yes	No
e)	S's reports are consistent with borderline personality disorder; e.g., frantic efforts to avoid real or imagined abandonment, unstable relationships.	Yes	No
f)	S's reports are consistent with depression; e.g., depressed mood, diminished interest, insomnia.	Yes	No
g)	S's reports are consistent with a disorder not otherwise specified. S is so paralyzed by pain that life, future, etc. is colorless and unattractive.	Yes	No

V - Weakened Resilience (Ego)

16)	There is a relative weakness in S's capacity for developing constructive tendencies (e.g., attachment, love). (D)	Yes	No
17)	There are unresolved problems ("a complex" or weakened ego) in the individual; e.g., symptoms or ideas that are discordant, unassimilated, and/or antagonistic. (P)	Yes	No
18)	S reports that the suicide is related to a harsh conscience; i.e., a fulfillment of punishment (or self-punishment). (D)	Yes	No

RELATIONAL

VI - Interpersonal Relations

19)	S's problem(s) appears to be determined by the individual's history and the present relational/interpersonal situation. (P)	Yes	No
20)	S reports being weakened and/or defeated by unresolved problems in the interpersonal field (or some other ideal such as health, perfection). (P)	Yes	No
21)	S's suicide appears related to unsatisfied or frustrated needs; e.g., attachment, perfection, achievement, autonomy, control. (P)	Yes	No

22)	S's frustration in the relational field is exceedingly stressful and persisting to a traumatic degree. (P)	Yes	No
23)	A positive development in the disturbed relations was seen as the only possible way to go on living, but such development was seen as not forthcoming. (P)	Yes	No
24)	S's relations(hips) (attachments) were too unhealthy and/or too intimate (regressive, "primitive"), keeping him/her under constant strain of stimulation and frustration. (D)	Yes	No

VII - Rejection - Aggression

25)	S reports a traumatic event or hurt or injury (e.g., unmet love, a failing marriage, disgust with one's work). (P)	Yes	No
26)	S, whose personality (ego) is not adequately developed (weakened) appears to have suffered a narcissistic injury. (P & D)	Yes	No
27)	S is preoccupied with an event or injury, namely a person/ideal who has been lost or rejecting (i.e., abandonment). (D)	Yes	No
28)	S feels quite ambivalent, i.e., both affectionate and hostile towards the same (lost or rejecting) person/ideal. (D)	Yes	No
29)	S reports feelings and/or ideas of aggression and vengefulness toward him/herself although S appears to be actually angry at someone else (ideal/object). (D)	Yes	No
30)	S turns upon the self, murderous impulses that had previously been directed against someone else. (D)	Yes	No
31)	Although maybe not reported directly, S may have calculated the self-destructiveness to have a negative effect on someone else (e.g., a lost or rejecting person). (P)	Yes	No
32)	S's self-destructiveness appears to be an act of aggression, attack, and/or revenge towards someone else (ideal/object) who has hurt or injured him/her. (P)	Yes	No

VIII – Identification - Egression

33)	S reports in some direct or indirect fashion an identification (i.e., attachment) with a lost or rejecting person (or with any lost

	ideal [e.g., health, freedom, employment, all A's]). (D)	Yes	No
34)	An unwillingness to accept the pain of losing an ideal (e.g., abandonment, sickness, old age), allows S to choose, even seek to escape from life and accept death. (D)	Yes	No
35)	S wants to egress (i.e., to escape, to depart, to flee, to be gone), to relieve the unbearable psychological pain. (P)	Yes	No

Abstract

Recent reports published by the Centers for Disease Control and Prevention indicate that suicide rates have been consistently rising in the United States across various cultural, socioeconomic, and racial groups. It is also estimated that 70% of adults in the United States have experienced a traumatic event at least once in their lifetime. Of those affected, as many as 20% will go on to develop post-traumatic stress disorder (PTSD). Studies have shown that individuals who are diagnosed with PTSD are at increased risk for death by suicide. However, the current literature also indicates that a diagnosis of PTSD in and of itself does not inherently place a person at increased risk for suicide. Given that a majority of the population has experienced a traumatic event, it is paramount that mental health clinicians evaluate their patients for risk of suicide as well as protective factors. The association between trauma events and suicide cannot be ignored. Mental health clinicians should be trained to assess for risk of suicide and know how to

appropriately intervene when suicidality is detected. When evaluating suicide risk, it is crucial to consider a variety of factors such as comorbid psychiatric diagnoses, level of impulsivity, gender, age, occupation, gender identity, and social support. This chapter describes risk factors for suicide in people who have experienced trauma. Additionally, assessments, interventions, and treatments for traumatized people at risk for suicide are reviewed.

Suicide and Trauma: Risk, Identification, and Treatment

In the last two decades, suicide rates in the United States have increased at an alarming rate [23]. From the dawning of the new millennium in 1999 to 2018, suicide rates increased by a staggering 35% [23]. Death by suicides rose steadily at 1% per year until 2006 when it doubled to 2% growth per year until 2018 [22]. Distressingly, suicide ranks as the second highest cause of death in the United States for people between ages 10 and 34 and fourth for those between 35 and 54. Across age groups, suicide is the tenth leading cause of death in the United States. It is evident that despite national objectives aimed at reducing suicide rates, suicide remains a public health crisis [56].

A proposed explanation for the uptick in suicide rates is an increase in psychological disorders. While this answer is speculative, the association between experienced trauma and suicide cannot be ignored. It is estimated that as much as 70% of adults in the United States have experienced a traumatic event at least once in their lifetime, and as many as 20% develop posttraumatic stress disorder (PTSD). As the majority of the population has experienced a traumatic event, it is paramount that clinicians pay special attention to the association between experienced trauma and suicide. In educating clinicians to assess for risk of suicide and to successfully intervene, much attention is paid to PTSD, as studies have shown that individuals with diagnoses of posttraumatic stress are often at increased risk for suicide. However, the current literature establishes that a diagnosis of PTSD alone does not inherently mean increased suicide risk. Various factors have been identified in increasing the risk of suicidality in patients diagnosed with PTSD. When evaluating suicide risk in patients, it is crucial to consider a variety of factors, including comorbid psychiatric diagnoses, level of impulsivity, gender, age, occupation, gender identity, and social support.

Suicide Risk

Comorbid Psychiatric Diagnoses

As noted, PTSD is associated with increased rates of suicidality [45]. However, PTSD can be comorbid with a variety of other mental health conditions and symptoms, each with its own compounding effects of suicidality and suicide risk.

For example, comorbid depression was found to strengthen the relationship between PTSD and depression in a 2012 meta-analytic study conducted by Panagioti and colleagues. There is also some evidence of anxiety disorders being associated with increased suicidal ideation, attempts, and behaviors [30].

Impulsivity

Impulsivity is generally defined as “a predisposition for rapid actions without appropriate foresight” [13]. Although a general understanding and consensus for this definition exists, studies exploring impulsivity as a construct have noted multiple facets. These facets are response inhibition, cognitive inhibition, and delayed/probabilistic discounting. The process in impulsivity, where previously planned behavior is negated, is known as response inhibition, while the negation of mental processes – intentionally or unintentionally – is known as cognitive inhibition [35]. The discounting facet of impulsivity relates to tendencies to making immediate decisions in situations, whether it be choosing immediately available small resources over delayed larger resources (delay discounting) or choosing larger resources that are less likely to be actually attained over smaller resources that are more likely (probabilistic discounting; [35]).

PTSD is recognized as having arousal-based symptoms that are impulsive in nature, such as increased engagement in self-destructive behavior and aggression [1]. Additionally, some research in the field has noted relationships between PTSD and impulsivity, with the severity of PTSD symptoms associated with impulsivity and behavioral impulsivity [59]. Impulsivity has long been associated with suicide, as well as with other behaviors that have significant relationships with suicide, such as non-suicidal self-injury [33].

A meta-analysis conducted by McHugh and colleagues in 2019 found that behavioral manifestations of impulsivity, namely, deficits in inhibitory control, prediction interval, and decision-making, had significant associations with suicidal behavior. Small to medium effect sizes were found regarding the relationship between behavioral impulsivity and suicide attempts [33].

Gender

In examining the rising rate of suicide, it is important to note contextual factors. In the most recent Centers for Disease Control and Prevention [7] report on suicide, cisgender males died by suicide at 3.7 times the rate for cisgender females, with males over the age of 75 being at the highest risk for suicide. Among females, those in the age range of 45–64 were most likely to commit suicide [7]. Of note, recent literature on cisgender females who engage in non-suicidal self-harm found that this likelihood was small based on analysis of 28 publications [57]. Comparing individuals who attempt suicide against those who only have ideation, gender does not appear to have a central role [34].

However, far greater than their cisgender counterparts, transgender individuals are recognized as having significantly higher risks for trauma, PTSD, and suicidality. Based on a study conducted in 2016, it was estimated that the prevalence of violence or victimization against this population is approximately 44% [46]. In a larger scale study conducted by James et al. [27], 40% of their transgender adult sample reported having made a suicide attempt, with 92% of these attempts being before the age of 25.

Age

When discussing the relationship between trauma and suicide, childhood trauma cannot be overlooked. In childhood, trauma and traumatic experiences can take many forms, all of which relate to suicidality. Research over the last 10 years has demonstrated how the presence of childhood trauma, specifically sexual abuse, physical abuse and neglect, and emotional abuse, have associations with suicidality and suicide attempts [60]. Recent meta-analytic investigations have identified that childhood sexual abuse, in particular, increases one risk for suicidality, specifically in an increase in risk for attempting suicide [44]. The effects of these childhood traumas can also have differential effects depending on the characteristics of the individual. For individuals with bipolar disorder, the presence of childhood maltreatment is a particularly robust risk factor, with those who had attempted suicide having significantly higher frequencies of childhood trauma and maltreatment [14]. In youth involved in the legal system, a trauma in childhood is one of the most noted correlates with suicidal ideation and behavior in several studies conducted over the last 20 years [53].

Trauma in childhood need not be committed directly against the child. Based on a study conducted in 2011 by Hamby and colleagues [20], it was estimated that one in four youths witnesses a violent act in their lifetimes. Additionally, one in ten youths reported witnessing a family member assault another family member, such as in the case of intimate partner violence (IPV). The presence of IPV has drastic effects on one's suicide risk, with youth exposed to IPV having twice the likelihood of attempting suicide than those who are not exposed [6].

Occupation

Though not often considered in the context of trauma and suicide, occupation and respective duties can play a role in suicidality. Specifically, occupations that expose an individual to potentially morally injurious events (PMIE) may impact suicidality. Occupations such as military service members, police officers, emergency medical personnel (e.g., EMTs, paramedics), and medical staff (e.g., nurses) may have to engage in tasks or work in situations where their required duties are not aligned with their moral belief systems [32, 40, 52].

Much of the research to date has focused on the experience of moral injury in military service members. Serving in the military can expose a person to a variety of PMIE, including but not limited to events experienced in combat. Litz and colleagues [32] list several such experiences, including the responsibility of taking a life, following orders to direct fire at enemy combatants, and witnessing violence and death among non-combatants [32]. In the same vein, first responders and medical personnel are also faced with morally questionable situations in the line of duty that may lead to increased suicidality. As protectors of the public, first responders can experience moral injury when they fail, subjectively or objectively, to protect others from harm. Such examples may include police investigation into crimes against children, sexual assault, or domestic violence. As research on moral injury has advanced, occupations outside the realm of military and law enforcement have

been examined. Within the medical field, the experience is so commonplace that the field of nursing has adopted the term “moral distress” [28] to describe the distress experienced when systematic constraints make it impossible to act in accordance with what one believes is right [40]. In their systematic review, Morley and colleagues [40] found that nurses all over the world reported experiencing moral distress.

In their preliminary model on moral injury, Litz and colleagues [32] posit that as a result of experiencing a potentially morally injurious event, a person’s worldview can shift dramatically [32]. A person may make increasingly negative evaluations about themselves, other people, and the world at large, leading to feelings of guilt and shame, potentially increasing suicide risk [32]. It is integral to the assessment of suicide to consider if a person may be experiencing moral injury, particularly if one’s subject has an occupation with increased risk of exposure to PMIE.

Another occupation that may be associated with an elevated risk of suicide is humanitarian workers, possibly due to vicarious trauma and morally injurious experiences. Humanitarian workers, such as staff serving in national and international organizations like the Red Cross and UN, were found to have a high prevalence of PTSD, depression, and anxiety-related symptoms [54]. With the already discussed associations between mental health conditions associated with trauma, it can be suspected that these conditions come with elevated suicide risk, though this requires further study.

Finally, another factor related to occupation and increased suicide risk is socioeconomic status. A study that analyzed the outcomes of 34 studies found that compared to the general population of employed individuals, suicide risk was highest in blue-collar workers, particularly workers in the ISCO classification group 9 (e.g., laborers, cleaners, machine operators) [37]. As the authors note, this could be explained by the social and economic disadvantages that come with blue-collar occupations, such as lower income. Socioeconomic status has been shown to be a significant predictor of suicidal behavior [37].

Social Support

Literature on social support over the last several years has shown significant protective elements and benefits in the reduction of symptoms associated with PTSD, suicide, and other conditions that are associated with suicide risk. In a meta-analysis exploring the impact of social support on mental health symptoms following a traumatic loss, clear negative relationships between social support and mental health conditions, PTSD, and depression were found [50]. Other meta-analyses have shown this protective relationship is consistent in other traumatic situations, such as situations with continuous traumatic experiences [20].

Ethnic Minority Status

Research has found that immigrants and ethnic minority groups pose a higher risk for suicidal behaviors and deaths by suicide, possibly due to acculturative stress, cultural conflicts, and socioeconomic difficulties [17]. For traumatic events and

posttraumatic stress symptoms among ethnic groups in the United States, Roberts et al. [48] examined 34,075 US residents and found that African-Americans have the highest rate of lifetime prevalence of PTSD, followed by Latinx, White, and Asian-Americans, respectively. However, White Americans have the highest endorsement of exposure to traumatic events [48]. The types of traumatic events also differ across ethnic groups: African-Americans and Latinx Americans have a higher rate of childhood maltreatment than White Americans, and Asian-Americans have a higher risk of war-related events than all other groups [48]. Notably, ethnic minority groups are less likely to seek mental health treatment for both PTSD [48] and suicidal behaviors compared to Whites [17].

The COVID-19 Pandemic

Following the start of the COVID-19 pandemic in the United States in early 2020, the US population has experienced a series of negative events, including but not limited to economic stress, fears associated with exposure to the COVID-19 virus, social distancing and quarantine, and possible mental health treatment barriers, among many others. It has been suggested that economic stress may lead to an increase in the suicide rate [36], but national mortality data remains unavailable at this time. In discussing the impact the coronavirus pandemic has had on suicide rates, it is essential to note the limitations of current studies. Due to the ongoing nature of the pandemic, definitive rates are not yet available. Nonetheless, within the United States, state-wide analyses of deaths by suicide can shed light on the question of how COVID-19 has impacted suicidality and traumatic stress. Interestingly, two state-wide studies of deaths by suicide in Connecticut and Maryland have both shown a decrease from early to mid-2020 compared with previous years [4, 38]. However, both studies also show that while the number of deaths by suicide for White people decreased, among people of color in Connecticut and African-Americans in Maryland, deaths by suicide increased [4, 38]. This phenomenon can likely be attributed to the disproportionate effects of COVID-19 on ethnic minority groups. Marginalized communities may have disproportionately high economic difficulties, exposure to higher-risk work environments, and less access to healthcare [55]. As a result, amidst the possible rise of deaths by suicide, there are also higher rates of death from COVID-19 in African-Americans, Native Americans, and Latinx Americans [55].

Identification

Identifying when a person is at increased risk for death by suicide is a crucial component of clinical training for providers. A breadth of research focused on identifying risk factors for suicide has given clinicians guidelines on how to best approach suicide risk. In such evaluations, both risk and protective factors are considered to influence overall risk. Despite having guidelines in place, identifying suicide risk is complex in that risk and protective factors can be highly individualized and may fluctuate. When identifying what factors make a person at increased

risk for death by suicide, it is important to know that the presence of trauma or PTSD is not a single indicator of suicide risk. Because trauma alone is not the only predictor of suicide risk, intersecting factors must be considered to more effectively identify and treat suicidal ideation.

Identifying risk for suicide is often a stressful and anxiety-provoking experience for clinicians. One of the strongest factors for suicidal behaviors (e.g., suicidal ideation, plan, intent, and attempt) is the presence of a mental health disorder [21]. Research suggests that more than 90% of those who die by suicide have a mental health disorder meeting clinically significant threshold [3]. Specifically, major depressive disorder and borderline personality disorder both include suicidal behaviors as specific diagnostic criteria [1]. Of note, although having experienced trauma increases suicide risk, suicidal thoughts and behaviors are not included among the diagnostic criteria for PTSD. As mentioned previously in this chapter, while the overwhelming majority of mental health diagnoses do not include suicidal behaviors as a diagnostic criterion, suicidal behaviors are not exclusive to major depressive disorder and bipolar disorder and maybe comorbid with other mental and physical health problems. For example, the presence of hopelessness has been strongly correlated with suicidal behaviors [5, 49], which is not exclusive to a mental health disorder and may be present even in the absence of a mental health diagnosis. Due to the high prevalence of mental health disorders and suicide risk, all healthcare workers play a vital role in assessing suicide risk and ensuring patient safety.

There has been a long-standing fear that talking about suicide with patients may lead to an increase in suicidal behaviors. This fear put providers into a precarious situation as they strove to assess for suicide risk without potentially increasing suicidal behaviors by inquiring about suicide. Cha et al. [8] examined the iatrogenic risk of behavioral measures of suicide, specifically the suicide or self-injury Implicit Association Test (IAT). This test involved exposing participants to rapid and repeated images and words related to suicidal behaviors. They found that based on the IAT, there was no reliable increase in suicidal behaviors across participants in the three variations of this research study [8]. Contrary to many initial beliefs about the iatrogenic effects of discussing suicide with a patient, this research supports the notion that merely talking about suicide with patients will not elevate suicide risk.

Assessing suicide risk is comprehensive and involves integrating multiple sources of information to determine the level of suicide risk as either low, moderate, or high. This assessment should also include the evaluation of both static risk factors, things that cannot be changed, and dynamic risk factors, which are factors that can be modified. One of the greatest tools to predict the risk of suicidal behaviors is simply through direct inquiry [3]. It is important to emphasize matter-of-factness without judgment or criticism when directly asking about suicidal behaviors [3]. Additional recommendations for assessing suicide risk are to conduct a diagnostic evaluation and chart review, obtain a family medical history, and determine both risk factors and protective factors for suicidal behaviors.

While there are many suicide self-report measures, researchers recommend that they be utilized as supplementary tools in a risk evaluation [3], alongside clinician-administered interviews. This is because suicide self-report measures have been

found to have poor generalizability and may not be appropriate for elder and minority populations, high false-positive rate, and low predictive validity [3]. Furthermore, many established suicide assessment measures do not take unique cultural factors into account. An important component of identifying suicide risk was to consider how marginalized groups experience continual traumatic events through various forms of distress. For example, substantial research on sexual minorities has shown that lesbian, gay, and bisexual people are at greater risk for suicidal behaviors than their heterosexual counterparts [19, 31]. The cultural theory and model of suicide integrates four factors specific to culture and suicide risk – cultural sanctions, idioms of distress, minority stress, and social discord, into a theoretical framework [10]. This framework then leads to the development of the Cultural Assessment of Risk for Suicide (CARS), a culturally informed self-report measure that is aimed at identifying suicide risk among ethnic and sexual minority groups [11]. The CARS identifies eight meaningful areas of cultural suicide risk and has been shown to provide useful information on suicide risk for the general population [11].

When working with a patient who has a PTSD diagnosis, there are some additional considerations clinicians should take into account when assessing for suicide risk. The DSM-5 categorizes symptoms of PTSD into four symptom clusters – alterations in arousal and reactivity, intrusive thoughts and memories, avoidance, and negative alterations in cognition and mood [1]. Because there have been mixed results produced by research examining the connection between specific symptom clusters and suicide risk, Chou et al. [9] studied the difference between the four-factor model of PTSD symptoms, in conjunction with the four symptom clusters, with a seven-factor model. The seven-factor model includes reexperiencing, avoidance, negative affect, anhedonia, externalizing behaviors, anxious arousal, and dysphoric arousal symptom clusters [9]. Chou and colleagues argued that the seven-factor model of PTSD has greater specificity to deepen understanding of psychiatric comorbidities, in this case, suicidal behaviors (2020). The seven-factor model showed that reexperiencing feelings, negative affect, anhedonia, and externalizing behaviors were all found to be associated with suicidal ideation, anhedonia being the strongest association [9]. While the association between symptom clusters and suicide risk is not fully understood, these symptom clusters can be utilized in clinical settings to guide providers in identifying suicide risk. Risk evaluations are not merely completed during the initial stages of treatment. Rather patients should be continually evaluated throughout treatment, especially those who have experienced trauma.

Treatment of Suicidality and Posttraumatic Symptoms

Treatment of suicidality and posttraumatic symptoms can be divided into three phases: treatment of acute suicide risk, stabilization, and trauma-focused treatment.

Treatment of Acute Suicide Risk

When encountering acute suicide risk, a clinician must determine the level of suicide risk to decide whether to admit the patients into inpatient or outpatient care [43]. The advantages of inpatient care include continuous care and observation and having a multidisciplinary team, while the disadvantages include loss of freedom and possible therapeutic rupture [58]. One way of determining the appropriate level of care for acute suicide risk is to assess whether the patients has adequate social support; if they do, then outpatient care may be a more viable option [58]. Regardless of treatment settings, the primary recommendation is for the clinician to immediately create and implement a treatment plan that targets the reduction of acute symptoms, which may include pharmacological treatment [58]. Note that the clinician or the hospital should monitor the patients closely while giving them medications in small portions to prevent overdosing [22].

Stabilization

In an inpatient setting, the clinician should start planning transitioning to outpatient care and collaborate with the site prior to discharge because the transitional period in which patients move from intensive care to a lower level of care setting is critical: the suicide death rate of patients leaving inpatient psychiatric settings is 300 times higher than the general population in the first week after discharge [12]. Knowing the increased risk during the transition from a higher to a lower level of care, strict follow-up and close monitoring of patient's post-discharge are important in maintaining patient safety. It is important for the clinician to develop a safety plan with the patient, listing out warning signs, internal coping strategies, things that can distract the patient, people to ask for help, and agencies to contact [51]. This safety plan can help provide support to the patient post-discharge by providing them with resources and a guide to seek help.

Aside from managing suicide risk consistently, the patients can also go through the stabilization phase for treating trauma, which involves developing coping skills for the subsequent trauma-focused treatment. Stabilization includes ensuring the patient's safety, providing psychoeducation on trauma and PTSD, and developing the patient's emotional and social coping skills so that they may be more resourceful in managing the intensity of trauma-focused treatment [25]. Researchers hold various views on the inclusion of the stabilization phase into treating traumatic symptoms: Jongh et al. [29] posit that adding a stabilization phase into treating complex PTSD may delay the patient's timely trauma-focused treatment.

Trauma-Focused Treatment

The American Psychological Association [2] has recommended four trauma treatment interventions with strong research support. The first, cognitive behavioral therapy (CBT), serves as the basis for all empirically based treatment recommendations. CBT emphasizes the relationship between thoughts, feelings, and behaviors and aims to change patterns within this aptly christened triangle that impacts a person's functioning [39]. CBT for PTSD aims to address unhelpful patterns of

thinking, called cognitive distortions, as well as implementing behavioral changes to create more balanced cognitions and behaviors to improve PTSD symptoms [39]. CBT for PTSD typically consists of 12–16 sessions and can be delivered via individual or group therapy [39].

Cognitive therapy (CT), derived from CBT, can also be used to treat PTSD. CT differs from CBT in that it does not address behavioral components and instead posits that PTSD develops if a person makes consistently negative cognitive evaluations about their trauma [15]. Through CT, a patient first learns to identify their maladaptive evaluations regarding the trauma and then modify these appraisals to be more effective and balanced [15].

Furthermore, there are two treatments generally accepted as the gold standard of trauma processing treatment: cognitive processing therapy (CPT) and prolonged exposure (PE). In PE, the patient is repeatedly exposed to thoughts, emotions, and situations related to their traumatic experience [16]. Through repeated exposure, the power the traumatic event holds to cause distress, and subsequent symptoms of PTSD, is significantly reduced [16]. In CPT, the focus of treatment is on cognitive restructuring or changing the content of thoughts about a person's experienced trauma [47]. Throughout the course of CPT, a patient's beliefs about "why" the trauma occurred, as well as how the trauma impacts their beliefs about the world, other people, and themselves, are addressed and processed through the use of worksheets [47]. Lastly, for individuals with comorbid PTSD and substance use disorders (SUD), the modality Seeking Safety for PTSD and SUD has strong empirical support [26, 41, 42, 61].

There are also several trauma interventions that the American Psychological Association recommends on a conditional basis. These include Eye Movement and Desensitization and Reprocessing Therapy (EMDR), the efficacy of which has been hotly debated within clinical researchers but has been growing steadily over the past several years. Other conditionally recommended therapies include brief eclectic psychotherapy and narrative exposure therapy (NET) [2].

These recommended treatments are not the only interventions used by clinicians to treat trauma and its associated symptoms. There are many emerging treatments for trauma. Clinicians should pay careful attention to both empirical evidence and support for new interventions as well as considering their patients' preferences when developing their treatment plan.

Conclusion

Suicide rates within the United States have steadily increased during the past two decades, making death by suicide a national crisis. The growing suicide rate has led to a plethora of research focused on identifying risk and protective factors to best address this crisis. While numerous risk factors have been identified, having experienced a traumatic event is a significant risk factor that cannot be ignored. When assessing suicide risk, providers must also consider a host of factors such as life circumstances and stressors, race, gender, age, social support, and how these factors overlap with trauma and suicide risk. The next step in addressing this crisis is to

provide support and treatment to reduce suicidal behaviors and help the patient cope with their past trauma. Where the patient receives treatment may vary depending on the severity of the suicide risk. Treatment can include hospitalization, stabilization, and trauma-focused treatment to promote long-term treatment gains and reduce suicidal behaviors in the future. Despite the increased suicide rates, more research alongside enhanced assessment and treatment options have helped address this growing issue.

suicidal behavior [3]. According to the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition* (DSM-V), psychotic depression is categorized as major depressive disorder with a specifier of psychotic features; these psychotic features may be coded as either mood-congruent or mood-incongruent [1]. The presentation of major depressive disorder without delusions or hallucinations will be coded without psychotic features and is often referred to as non-psychotic depression throughout the literature.

Major depression is a debilitating disorder characterized by low mood, anhedonia, hopelessness, sleep disturbances, weight loss/gain, and potentially self-harming behavior. An individual that suffers from psychotic depression will meet the criteria for major depressive disorder while simultaneously experiencing elements of psychosis, which typically elevate severity levels and the risk of suicidal behavior [3]. According to the *Diagnostic and Statistical Manual of Mental Disorders, fifth edition* (DSM-V), psychotic depression is categorized as major depressive disorder with a specifier of psychotic features; these psychotic features may be coded as either mood-congruent or mood-incongruent [1]. The presentation of major depressive disorder without delusions or hallucinations will be coded without psychotic features and is often referred to as non-psychotic depression throughout the literature.

Symptomatology

An individual presenting with mood-congruent psychotic features will experience delusions and/or hallucinations that align with the themes of their depression, such as personal inadequacy, guilt, death, or deserved punishment [1]. For example, an individual may report experiencing an auditory hallucination in which a voice tells him or her that he or she is worthless. Alternatively, the mood-incongruent specifier applies to individuals that experience delusions and/or hallucinations that do not align with depressive themes, or perhaps a mixture of both types of psychotic features [1]. In addition to the positive symptoms of delusions and hallucinations, individuals with psychotic depression can exhibit negative symptoms and cognitive difficulties. Negative symptoms of psychosis can include catatonia, flat affect, disorganized or derailed speech, incoherent speech, and disorganized behavior [1].

Numerous biopsychosocial risk factors of psychotic depression have been identified, and these risk factors tend to overlap with those of schizophrenia. For instance, an individual may be vulnerable to developing this disorder because they have a history of mental illness and/or psychosis in the family [17]. Additional risk factors associated with a diagnosis of psychotic depression include living alone, experiencing childhood adversity or trauma, having little social support and confidants, being unemployed, and having more neurological soft signs as evidenced by assessments such as the Neurological Evaluation Scale [17]. Further, a prominent biological risk factor for depression is the hyperactivity of the hypothalamic-adrenal-pituitary axis function in the brain, causing elevated stress hormone levels of

cortisol. This association is especially strong for individuals who present with psychotic features [29]. Higher cortisol levels are typical within this population of patients, which is associated with more severe neurocognitive functioning, especially in the domains of working memory and verbal memory [12].

Biological Symptoms

The presence of psychotic features also plays a significant role in the course of one's illness, with psychotic episodes lasting longer than non-psychotic episodes, heightened severity, more significant psychosocial impairment, and fewer periods of minimal symptoms [7]. Using recent data collected by The Mental Health in the General Population Survey, Benard et al. [3] also determined that a history of a depressive episode with psychotic symptoms is more frequently linked to a suicide attempt when compared to depression without psychotic symptoms. Comorbid psychiatric disorders are also more common in participants who report psychotic features, meaning that the risk for mania, substance use disorders, and anxiety may also be elevated for individuals with psychotic depression [3]. Therefore, severity levels of depression are highly variable between individuals who experience psychotic features and those who do not.

Severity of symptoms appear to be greater in patients with psychotic depression, primarily because of reported severe psychomotor difficulties ([20]; Thakur et al. 1998). Psychomotor retardation is a long-established component of depression and is one of the core symptoms identified to diagnose major depressive disorder (MDD [6]). Psychomotor agitation is assessed through behavior observations of posture, facial expression, degree of movements, and speech, which has been extensively studied in the context of depression [6].

Functional Impairments and Cognition

Research has found that patients with major depressive disorder with psychotic features compared to healthy controls and patients with non-psychotic major depressive disorder have more significant deficits in various cognition tests [20]. Functional impairment in major depression is attributed to many factors, including mood disturbances, cognitive dysfunction, and psychomotor retardation, among others [33]. Deficits in cognition were observed to be more severe in working memory, language, and executive functioning [12, 33]. This suggests that even though patients with psychotic depression are able to attend to information, they have increased difficulty in processing, manipulating, and encoding new information [12]. Further, Gomez et al. [12] found correlations between executive functioning and cortisol, specifically in working memory.

Rothschild et al. [24] found higher cortisol levels in the afternoon in patients with psychotic depression than schizophrenia, thus concluding that the increase of cortisol levels was likely due to the presence of psychosis in the context of an affective

disorder than just psychosis on its own [24]. Individuals with psychotic depression, when compared to those with schizophrenia, also fare worse in symptom severity related to psychomotor speed, motor skills, and displayed cognitive deficits [18]. A study by Stetler and Miller [29] found cortisol levels in patients with psychotic depression to be nearly half of a standard deviation greater than patients with non-psychotic depression.

Though more research is needed, the implications of distinguishing between psychotic and non-psychotic depression are important as complaints of concentration and memory problems can be indicative of increased impairment in working memory and other executive functioning in patients with psychotic depression [12]. Therefore, a brief neuropsychological assessment may help clarify cognitive issues and alert clinicians to underlying reasons for cognitive deficits [12]. With a lifetime prevalence of 5–20%, it is common that individuals with major depressive disorder will spend a large portion of their lives battling symptoms and dealing with functional impairment both at home and at the workplace [33].

Psychotic Depression vs. Non-psychotic Depression

Psychotic depression is estimated to be present in approximately 25% of hospital admissions; however, it often goes overlooked because patients tend to underreport symptoms of psychosis and clinicians fail to properly assess [11]. Compared with non-psychotic depression patients, psychotic depression patients experience symptoms characterized by greater severity, psychomotor disturbances, cognitive impairments, interpersonal problems, and suicidality [11]. Though there has been significant progress made in the last two decades in understanding psychotic depression, research suggests that psychotic depression and non-psychotic depression are different syndromes, with various biological features, treatment response, and clinical course [20]. A study reported that almost all forms of severe depression were associated with higher rates of psychosis at 33%. However, those with mild to moderate severity also demonstrated high rates at 15% and higher [22].

A study showed psychotic depression patients performed significantly worse than the non-psychotic depression patients on most neuropsychological assessments (e.g., WAIS-R, California Verbal Learning Test, Trail Making, grooved pegboard story learning, and figure learning) despite having comparable age, education, and severity of depression [18]. In the cognitive ability areas, significant differences were seen in psychomotor speed, motor skills, and attention. The authors suggested that these differences were independent of the disorder's severity and, instead, trait-related [18].

Though severe depression alone does not count for the presence of psychotic symptoms, those with psychotic symptoms do appear to have more severe cases of depression [20]. As evidence has supported the use of “psychosis” as a specifier, Keller et al. [20] recommend that the specifier be separate from the “severity” specifier as it is possible to experience psychotic depression at less severe forms. Furthermore, they also recommended more precise guidelines to distinguish between psychotic and non-psychotic elements of depression, such as guilt derived from hallucinations from illusion or non-delusional guilt [20].

Psychotic depression is also characterized by longer episodes and higher rates of relapse and recurrence and observable reduction in social and occupational functioning once symptoms have improved [31]. Differences seen between psychotic and non-psychotic depression patients have led researchers to tout the idea of classifying it as a distinct disorder due to the number of biological and behavioral symptoms and support for psychotic depression being biologically different from non-psychotic depression [11, 18, 28].

Treatment

Due to the severity of psychotic depression and the high incidents of suicide behavior attached to it, psychotic depression is usually treated within a medical setting to be able to monitor symptoms and suicide risk [8]. Overall, biological treatments in the form of antidepressants and antipsychotics are recommended to treat mood and psychotic symptoms. Farahani and Correll [8] conducted a study that suggests antipsychotic-antidepressant co-treatment is more effective than only antidepressant medication. However, numerous individual factors affect medications' efficacy, such as age and comorbid mental and medical conditions [4]. Most studies have also found that patients with psychotic depression tend to respond more poorly to antidepressant monotherapy than those with non-psychotic depression [31].

Antidepressants

Antidepressants are usually introduced as the first line of treatment for moderate to severe depression and psychotic depression [16]. In addition to helping people regain emotional stability, antidepressants help reduce additional symptoms such as sleep irregularities, restlessness, and lack of motivation and reduce suicidal thoughts [16]. By taking into consideration that depression is caused by chemical brain imbalances such as serotonin, antidepressants work by increasing and modulating the availability of such chemicals [16]. Different antidepressants target different chemical imbalances in different ways. Tricyclic monoamine oxidase inhibitors can have side effects such as dizziness and loss of coordination [16]. The selective serotonin reuptake inhibitors (SSRI's) such as fluoxetine have been reported to be effective in the disorder when combined with "Atypical antipsychotics" (Rothschild A. et al 2004; Meyers B. et al 2009).

Antipsychotics

Antipsychotic medications are often introduced to reduce symptoms of psychosis. Antipsychotics are medications that help regulate information in the brain derived from abnormal dopamine and other neurotransmitter transmissions [19]. By doing so, antipsychotics help the brain to organize information better and gain a clearer sense of reality. Also, it is essential to recognize when considering antipsychotics as a form of

intervention that antipsychotics are often classified into two classes, first-generation antipsychotics (FGAs), also known as “typical antipsychotics,” and second-generation antipsychotics (SGAs), also known as “atypical antipsychotics.” FGAs were developed initially in 1950 to treat psychotic symptoms of schizo-phrenia (Solmi et al. 2017).

Large scale trials have reported that SGA’s plus SSRI’s are significantly more effective than placebo or SGA alone in psychotic depression (Rothschild A. et al 2004; Meyers B. et al 2009). In contrast, in addition to treating psychotic symptoms, SGAs also help treat negative symptoms, which are the lack of ordinary positive mental activities such as social engagement, positive emotions, and motivation (Solmi et al. 2017). The caveat of antipsychotics is the side effects such as nausea, tardive dyskinesia (i.e., uncontrollable movements), weight gain, and even seizures (NIH 2020). However, individual differences and symptom severity would indicate if FGAs or SGAs are more appropriate [15]. It is crucial to maintain continuous appointments with the medication provider to assess the effectiveness and side effects of antipsychotics.

According to Schatzberg [27], the best course of treatment for psychotic depression is sometimes to use antipsychotics to stabilize the patient and then introduce antidepressants when the patient has stabilized and is more willing to accept treatment. A meta-analysis by Farahani and Correll [8] also found importance in treating psychotic depression with antipsychotics; however, they found the superior treatment was the combination of antipsychotic-antidepressant rather than the monotherapy of either medication.

Ketamine

A newer form of treatment that could be considered a potential treatment for psychotic depression is ketamine. Ketamine was originally developed as an anesthetic during the era of the Vietnam War (Torricelli 2020). However, it has also been an effective antidepressant among those that haven’t responded to other antidepressants and has a fast-acting mechanism of action that reduces symptoms of psychosis within hours (Ribeiro et al. 2016). However, the effects of ketamine are suggested to be less effective among individuals with a history of psychosis, and they may in fact experience a short-term increase in dissociative or psychotic symptoms [23].

Electroconvulsive Therapy

Another form of treatment for psychotic depression is electroconvulsive therapy (ECT). ECT can be defined as the use of brief electrical stimulation while the patient is under anesthesia, often administered by a team of medical professionals [21]. ECT is usually implemented on patients with therapy-resistant depression as well as psychotic depression (Fink, 2018). Although it is highly effective with remission rates of 95% for psychotic depression, due to the invasive nature of ECT, it is often used as a last resort option (Fink 2018). Wilcox et al. (2000) suggested that

individuals with a psychotic disorder are more likely to relapse than individuals with severe non-psychotic depression. However, people with psychotic depression can have good treatment outcomes and may be able to recover within months of starting treatment [4].

Prudic et al reported psychotics in major depression predicts positive acute response to ECT but also higher relapse rates in the month post completion of treatment concise (Biol Psych 2004). Follow-up treatment is usually indicated to prevent relapse [4]. Due to the increased risk of suicide and the potential use and changes of medications to decrease side effects, clear and ongoing communication with providers is highly encouraged [4]. Despite the efficacy of ECT treatment, its use has been limited by several considerations, including accessibility, cost, adverse cognitive reactions, and as noted above high rates of early relapse [31]. Therefore, psychopharmacological treatment should remain the first line of approach in treating psychotic depression [31].

Suicide

There is some suggestion that major depressive disorder with psychotic features has a higher morbidity and higher suicide rate [14, 20, 34]. The presence of delusions in an episode of major depression was associated with higher morbidity, as compared to non-psychotic depression, with longer duration of episodes with greater recurrence [20]. Higher mortality does not always indicate suicide, though it does increase risk factors associated with suicidality. Higher mortality rates in this population were also due to medical illnesses and other physical hazardous situations [32]. Additionally, higher levels of cortisol may have medical consequences in this population and put them at risk for conditions such as Type II diabetes, osteoporosis, or dementia [29]. Individuals with psychotic depression are also vulnerable to other diseases are associate with elevated of mortality rates, as well as situational dangers that can also contribute.

Studies in clinical and general populations have found depression to be the strongest predictor of suicide, and with the addition of psychosis and other features discussed earlier in the chapter, patients with psychotic depression present at very high risk for suicide behavior [9]. Schatzberg and Rothschild [28] discussed finding association between the presence of psychosis in patients with depression with more severe depressive symptoms, more frequent hospitalizations, worse short- and long-term course of the disorder, and greater number of suicide attempts compared to patients with non-psychotic depression.

In a study conducted to assess suicidality in patients with psychotic depression, that 59.6% of the sample reported current suicidal ideation or suicide attempt during their current depressive episode [26]. These findings are consistent with a previous study that identified suicidal ideation in 57% of patients with psychotic depression compared to 42% of non-psychotic depression patients [30]. Higher rates of lifetime suicide attempts were also seen in patients with psychotic depression, as 35.5% reported having made a lifetime suicide attempt [26]. Males were also found to be

more positively associated with suicidality in comparison to female's report of suicidal ideation [26].

A systematic review and meta-analysis of suicidality in individuals with psychotic depression found patients with psychotic depression to have significantly higher likelihood of a suicide attempt in their lifetime as well as during a major depressive episode than those with non-psychotic depression [14]. The review also found that individuals during the acute phase were 21-fold more likely to report a suicide attempt than in full remission phase [14].

Analyses revealed that younger age, psychomotor retardation, guilt, feelings of worthlessness, history of delusions in the past, and increased suicidal ideation and intent were found more commonly in psychotic as compared to non-psychotic depression [30]. Patients with psychotic depression have been found to have five times greater risk of dying by suicide than those with non-psychotic depression, though most recently a meta-analysis found the risk to be 1.21-fold in lifetime risk, as well as more likely to engage in violent methods of suicide attempt [14, 30]. Despite a shift in numbers, suicide risk continues to be significantly higher in individuals with psychotic depression than non-psychotic depression.

According to the meta-analysis done by Gournellis et al. [14], suicidal behavior and tendencies in patients with psychotic depression related to mood congruence, there are no differences compared to those with non-psychotic depression. However, patients with psychotic depression reported significantly higher levels of violent suicidal attempts and more severe outcomes, while those with non-psychotic depression had attempts that were less likely to be medically serious [14]. In another meta-analysis, the authors found on inpatient psychiatric units, suicide attempts for patients with psychotic depression were more frequent at 27.6% vs. 22.7% than for those with non-psychotic depression [34]. In the same study, the authors found the same trends in outpatient as 17.8% of patients with psychotic depression attempted suicide compared to 6.8% of patients with non-psychotic depression [34]. They also found this rate to be significantly lower than those in inpatient units [34]. The likelihood of completed suicide is also higher for patients with psychotic depression, and one study found those patients to be 5.3 times more likely to complete suicide than those with non-psychotic depression [14].

Overall, the findings indicated that during the acute phase or episode of psychotic depression, especially when a patient is hospitalized in an inpatient unit, the likelihood of a suicide attempt increases. It was also found that patients with psychotic depression have higher rates of suicide ideation, suicide attempts, and suicide completion than those with non-psychotic depression [34].

Role of Delusions and Hallucinations

A Research conducted to examine the relationship between psychotic symptom and suicide ideation and behavior found four themes derived from the patient's psychotic experiences related to suicidal behavior: (1) being "directed" to perform the suicidal behavior, (2) feeling "hounded" to death, (3) becoming "trapped" in "unescapable

darkness,” and (4) being left “bereft” of any mental control [9]. Participants in this study found it difficult to control impulsivity that was directed by delusions or hallucinations and felt they had minimal time between impulse and action [9]. Participants who reported command hallucinations stated they heard messages from gods or demons as well as visual and auditory hallucinations that instructed them to do self-harm [9]. Most reported overwhelming anxiety that caused them to want to escape those feelings [9]. A meta-analysis found late-onset psychotic depression compared to early-onset presents with more prevalent delusional beliefs of “somatic and impending disaster type” and that suicide risk might be differently associated with the type of delusion an individual experiences [14].

Conclusion

Psychotic depression is characterized by longer episodes and higher rates of relapse and recurrence, as well as observable reduction in social and occupational functioning once symptoms have improved. It is also relatively common as approximately 20% of patients with depression have psychotic depression. Numerous biopsychosocial risk factors of psychotic depression have been identified, for instance, an individual may be vulnerable to developing psychotic depression if they have a history of mental illness and/or psychosis in the family [17]. Additional risk factors associated with a diagnosis of psychotic depression include experiencing childhood adversity or trauma, having little social support and confidants, and having more neurological soft signs [17]. Further, a prominent biological risk factor for developing depression is the hyperactivity of the hypothalamic-adrenal-pituitary axis activity in the brain. This association is especially strong for individuals who present with psychotic features, higher levels of cortisol are also typical for this population [12, 29]. Higher levels of cortisol are associated with more severe neurocognitive functioning, especially in the domains of working memory and verbal memory [12].

Functional impairment in major depression is attributed to many factors including mood disturbances, cognitive dysfunction, and psychomotor retardation among others [33]. Deficits in cognition were observed to be more severe in working memory, language, and executive functioning [12, 33]. This suggests that even though patients with psychotic depression are able to attend to information, they have increased difficulty in processing, manipulating, and encoding new information [12].

Several studies discussed how difficult it may be to correctly diagnose and treat unipolar major psychotic depression, as it is often misdiagnosed as non-psychotic depression, schizophrenia, or bipolar disorder with the understanding that a manic episode has not occurred yet. This leads to prolonging symptoms for the patients, as well as not providing adequate treatment for the patients in a timely manner, which may increase the risk for suicide. Individuals with psychotic depression may feel the need to keep their psychotic symptoms to themselves during a first episode or in the beginning of the manifestation of psychosis, and unless it is appropriately assessed, they remain at high risk for suicide, as experiencing delusions and hallucinations may cause them to act on these thoughts. Despite several treatments for psychotic

depression, several studies have discussed the importance in treating psychotic depression with antipsychotics as one of the most important first line of treatment. Studies also found ECT can have a good treatment outcome and patients who receive this treatment may be able to recover within months of starting. Further, one study found the best course of treatment was the combination of antipsychotics and antidepressants rather than the monotherapy of either medication.

A longitudinal study that followed hospital admissions for 15 years found that patients with psychotic depression were twice as likely to die as their counterparts with non-psychotic depression (41% vs. 20%), though not all deaths accounted for were due to suicide; nonetheless the mortality rate is higher, and death by suicide was found to be of a more violent nature in those with psychotic compared to non-psychotic depression [32]. The risk of suicide is elevated in individuals with psychotic depression in both the acute phase of the disorder and over the lifetime; therefore, an early and accurate assessment and diagnosis are recommended not only for psychotic depression but for suicide ideation [14].

Important clinical implications continue to be derived from studies and meta-analyses linking patients with psychotic depression to higher likelihood of suicide. As such, there is strong evidence to show that impulsivity, strong feelings of guilt, shame, intense anxiety, and a chaotic mental state are risk factors for suicidal behavior in patients with psychotic depression [14]. To prevent impulsive suicidal behavior, findings highlight the need for a treatment approach focusing on modifying psychotic experiences and intense anxiety for patients [10].

Overall, findings have indicated that during the acute phase or episode of psychotic depression, especially when a patient is hospitalized in an inpatient unit, the likelihood of a suicide attempt increases. Patients with psychotic depression have higher rates of suicide ideation, suicide attempts, and suicide completion than those with non-psychotic depression. In summary, studies support categorizing psychotic depression as its own distinct disorder due to the number of biological and behavioral symptoms as well as psychotic depression being biologically different than non-psychotic depression.

Abstract

Historically, research has emphasized the importance of understanding various facets of suicidality. Researchers have prioritized studying overt suicidal behaviors (e.g., use of firearms) over covert acts (e.g., excessive substance use) largely in part due to the high lethality and urgency associated with overt suicidal behaviors. The often more indirect ways of accelerating death are less apparent but equally as detrimental. This chapter aims to illuminate the importance that indirect self-destructive behaviors have on an individual's overall well-being. It will underscore risk factors associated with indirect self-destructive behaviors and discuss clinical applications of treatment.

Introduction

Aspects of suicidality are foremost thought of as explicit acts to take one's life. This often includes violent acts of self-harm and those that directly expose oneself to lethal injury. Behaviors that are self-destructive in nature or inadvertently expedite death are often unnoticed, overlooked, or disregarded in terms of suicidality research. This is due in part to their subtle, covert nature, and indirect influence on expediting death. These behaviors are less apparent than explicit forms of suicide but can be just as detrimental.

Suicidal behavior is considered, within the literature, to be a dimensional construct that lies on a spectrum [1]. Suicidal ideation, non-suicidal self-injury, and indirect self-destructive behaviors, which do not immediately result in death but may lead to it due to continuous damaging effects, are found within this spectrum of suicidal behaviors [1]. The ends of this spectrum include failed suicides, death by suicide, and intentions to die on the one hand, and feelings of hopelessness, worthlessness, and depression on the other [1]. Unfortunately, research has prioritized the more severe ends of the suicidal behavior spectrum. This is likely in part due to the lethality and time-limited components associated with suicidal behaviors that immediately lead to death. Consequently, few publications have focused on the most common forms of indirect self-destructive behaviors despite their association with an increased risk of overt suicidal behavior [2, 3].

This chapter aims to resolve this by illuminating how indirect self-destructive behaviors impact an individual's overall well-being and hasten death. This chapter will discuss the complexities of common indirect self-destructive behaviors and highlight their unique characteristics. Mental health, societal, and medical risk factors associated with various indirect self-destructive behaviors will be discussed as well as treatment options or assessment considerations.

Overview and Background of Indirect Self-Destructive Behaviors

Indirect self-destructive behavior (ISDB) is defined as any long-term behavior engaged in knowingly or unknowingly with a disregard of expedited death that is not considered an act of suicide by the individual [4]. Indirect self-destructive behaviors can take many forms including, alcohol or drug use, cigarette smoking, behaviors of self-neglect, disordered eating behaviors related to bulimia or anorexia nervosa, various reckless and impulsive behaviors, excessive stress, and many others [5, 6]. The exact underlying mechanism that leads to the formation or engagement of

ISDBs is not concretely known in the literature, but some theories related to their development and engagement are available.

Research suggests that disturbances occurring during the formative years of adolescence related to traumatic experiences may result in the development of various ISDBs later in life [7–9]. Adults who experienced trauma in adolescence have also been shown to report more depression, anxiety, and various other psychological symptoms than those without a history of trauma, with some research indicating that emotion regulation difficulties mediated these effects [10, 11]. Emotion dysregulation may also play a role in the development of ISDBs as some of these behaviors have been found to be associated with maladaptive coping with psychological distress and a variety of negative emotions [12–14]. Lifetime experiences of trauma have been shown to be associated with some ISDBs, such as reckless and impulsive behaviors [15].

The engagement in some ISDBs may be related to various characteristics of personality [1]. Some personality characteristics that may be associated to ISDBs include risk-taking, excitement seeking, low self-esteem, a greater tendency for denial of problematic behaviors, poor social adjustment, a present-oriented perspective, and a predisposition for impulsivity [1]. Maclaren and Best [16] found that sexual promiscuity, substance use, and eating disorders were related to characteristics of impulsivity and the need for gratification. Differences between these behaviors were also found in that substance use was related to characteristics of denial while sexual promiscuity was related to characteristics of maladaptive cognitions. Eating disorders, however, were related to characteristics of low self-esteem. Despite these findings, there is not sufficient evidence to conclude that ISDBs are directly related to personality characteristic and further research should be conducted.

Gambling, sexual promiscuity, motor vehicle accidents, binge eating, alcohol or substance use, and reckless or impulsive behaviors are all acts that are indirect, self-destructive, and frequently engaged in in society [5, 6]. Some of these behaviors are thought to be an extension of those formed in adolescence wherein the learned behavior become ingrained or automatic by adulthood. However, this is not true for all ISDBs as other behaviors are expected to develop later in life [1]. The point in life at which an ISDB was developed can be a source of difficulty for providers when they attempt to parse out normative behaviors from chronic indirect self-destructive ones [1]. Coupling this with the broadness, vagueness, and seemingly commonplace practice of some ISDBs, conceptualizing how severely and frequently an individual engages in a specific ISDB can be challenging.

To identify a behavior as an ISDB the acceleration of death and the overall negative effect on well-being must be considered. ISDBs differ regarding the specific ways in which this occurs. This chapter will take a closer look at eating disorders, alcohol and drug use, reckless or impulsive behaviors, and self-neglect focusing on exactly how death is hastened, associated risk factors, effects on well-being, and treatment considerations are to be analyzed in order to provide a more nuanced look at common ISDBs on the spectrum of suicide.

Eating Disorders

An eating disorder is characterized by a consistent disturbance of eating or related acts that result in the modified absorption or consumption of food that considerably impairs physical or mental health [17]. There are various patterns of behaviors that fall within the definition of an eating disorder, the most common including bulimia nervosa, anorexia nervosa, binge eating disorder, and subthreshold eating disorders. Keski-Rahkonen and Mustelin [18] reviewed literature on the prevalence of these disorders in Europe and found a range of frequency in the conditions. Bulimia nervosa was reported by 1–2% of women, anorexia nervosa by 1–4%, binge eating disorder by 1–4%, and subthreshold eating disorders by 2–3%. About 0.3% of men reported any of these eating disorders and 0.7% reported subthreshold ones. The prevalence of eating disorders consistently appears to vary significantly by sex, with bulimia nervosa and anorexia nervosa being reported to occur at about a 10:1 female-male ratio. These sex differences are far less significant in those with binge eating disorder. Additionally, binge eating disorder differs from the other common eating disorders in that they are seen more readily in individuals seeking to lose weight [17].

The engagement in modified absorption or consumption of food that is seen in those with eating disorders can lead to a plethora of medical complications, and can be considered consequences of purging behaviors, starvation, or binge eating [19]. Purging behaviors can lead to cardiac arrhythmia, starvation can lead to cardiac muscle wasting, and binge eating can lead to esophageal or gastric ruptures. These complications are just a few of those that are possible as the result of engaging in these behaviors, and along with various other complications, may lead to or hasten death [19, 20]. Mortality rates for individuals with bulimia nervosa or an eating disorder not otherwise specified diagnosis are elevated in comparison to those without these diagnoses. Anorexia nervosa displays the greatest rate of mortality with an annual mortality rate of 5/1000 person-years [21]. Medical complications are not the only adverse effects seen in those who engage in this type of ISDB.

Those with a history of eating disorders have been found to be significantly more likely to report emotional and psychological problems [22]. Psychological and mental health issues are notable and various diagnoses are highly comorbid in those who engage in this ISDB. Individuals with anorexia nervosa have shown lifetime rates of comorbidity of 47.9% with any anxiety disorder, 42.1% with any mood disorder, and 27.0% with any substance use disorder. Bulimia nervosa has been shown to have similar results with lifetime rates of comorbidity of 80.6% with any anxiety disorder, 70.7% with any mood disorder, and 36.8% with any substance use disorder. Binge eating disorder follows a similar pattern with results of lifetime rates of comorbidity of 65.1% with any anxiety disorder, 46.4% with any mood disorder, and 23.3% with any substance use disorder [23]. While these psychological stressors are seen in congruence with common eating disorders and the associated negative consequences are apparent, the presence of these issues do not account for why this ISDB is developed. Other factors, however, have been associated with increased risk of eating disorders developing or being present.

As outlined earlier, females significantly outnumber males when it comes to the lifetime presence of an eating disorder, specifically for anorexia nervosa and bulimia nervosa. Various research has been conducted to attempt to explain why there is such a substantial difference in prevalence between the sexes; one explanation for these differences is societal influence. Epidemiological and cross-cultural research supports this explanation as findings emphasize the internalization of the thin ideal as a social risk factor that substantially contributes to severe weight controlling behaviors, which are the basis of eating disorders, in women [24]. Participation in activities that value thinness such as ballet, modeling, or gymnastics are also notable risk factors for anorexia nervosa. Additionally, socioeconomic status is associated with increased risk wherein middle- to upper-class females have a higher likelihood of being diagnosed with anorexia nervosa [25]. Adolescence has also consistently been found to be a risk factor in the development of eating disorders, specifically bulimia nervosa and anorexia nervosa. These disorders tend to occur during adolescence with a reduced likelihood of its onset later in life [23]. Lastly, genetics has been shown to be associated with the potential development of eating disorders. Familial and twin studies have demonstrated that genetic factors may influence the risk associated with the development or lifetime prevalence of anorexia and bulimia nervosa [26, 27]. Future research on genes and environmental influence is needed to isolate specific associated risks.

Lower life satisfaction and impaired emotional well-being has been found in college students with eating disorders, and showcases the need for intervention [22]. There are a variety of treatment methods to combat common eating disorders, but the most empirically validated forms of psychological treatment for bulimia nervosa, anorexia nervosa, and binge eating disorder are family-based treatments and cognitive behavioral therapy [28–31]. Treatments for disordered eating ISDBs are more focused on the associated disorders rather than underlying issues that may have facilitated their development. Family-based treatments are primarily designed for adolescents as they incorporate the parental figure and entire family unit as a source of support for the patient. The process is collaborative, but parental authority is needed due to the health crisis these disorders pose [32, 33].

The cognitive behavioral therapy (CBT) treatment for anorexia nervosa with the strongest efficacy focuses on relapse prevention following weight gain inpatient treatments, post-hospitalization. This treatment focuses on behavioral and cognitive features associated with maintaining problematic eating pathology [29]. CBT for bulimia nervosa directly targets binge eating, excessive concern with body weight and shape, and inappropriate compensatory behaviors. This treatment specifically focuses on addressing factors that promote the binge-purge cycle and the subsequent negative consequences [34]. CBT for binge eating disorder focuses on reducing dietary restraint through behavioral strategies as well as modifying distorted thoughts or beliefs about one's body weight or shape [35]. All these treatments prioritize immediate behaviors and cognitions that maintain problematic food intake patterns rather than potential emotion regulation difficulties that are associated with this ISDB [13]. This is done to immediately address the health concerns that arise from the continuous engagement of eating disorder related ISDBs which ultimately

lead to or hasten death. It is imperative for clinicians to remember that treatment of these disorders is paramount not only due to the negative aspects related to mental health, but also due to how death is hastened as a result from their engagement.

Substance Use

Various populations and cultures across the globe engage in the use of substances. The World Health Organization identified alcohol to be the most used psychoactive substance with the highest demand for treatment across the globe in 2010. Global trends indicated that alcohol and drug use was more common among males than females, and that the use of alcohol and drugs result in adverse global consequences [36]. A distinction in research exists between the use of a substance resulting in impairments and usage without such consequences [37]. Within the literature, the addictive and abusive use of substances is regarded as an ISDB due to the death hastening effects seen with continuous use [38]. Prevalence for substance use disorders (SUDs) vary by substance and region. Within the United States, 14.8 million people or 5.4% of the population 12 years or older met criteria for alcohol use disorder (AUD) in 2018. About 8.1 million people aged 12 years or older met criteria for illicit drug use disorder, which includes various substances such as heroin, cocaine, marijuana, methamphetamine, and prescription drugs [37]. Diagnostic criteria for the prevalence of the disorders listed utilized the DSM-IV. These prevalence rates highlight the commonality of the problematic use of these substances and underscore the need for these behaviors and their destructive consequences to be better understood. The prolonged use of substances is highly self-destructive and results in an extensive number of adverse effects related to physical health, mental health, and mortality.

Several notable problems arise that lead to or hasten death when substance use is engaged in as an ISDB. A multitude of medical complications and increased rates of mortality related to both unintentional overdose and motor vehicle accidents can occur as a result of this ISDB [39–43]. As alcohol is more commonly used than other forms of substances the destructive consequences that stem from its abuse are well-researched. The most notable medical complication with a clear association to the abuse of alcohol is alcoholic liver disease and cirrhosis [42, 44]. About 20% of heavy drinkers develop fatty liver which leads to hepatitis. With continued alcohol use about 40% of cases can develop into cirrhosis and the mortality rate at this time is approximately 50% [42]. Anywhere from 10% to 15% of people with AUD develop cirrhosis and survival depends on if consumption ceases upon diagnosis [42].

The negative medical effects that hasten death via the use of other substances is also documented. Drugs that can be administered via injection, such as heroin and cocaine, have been shown to result in death related to tetanus and hepatitis. Additionally, various infectious diseases are easily transmittable with the use of needles including tuberculosis, malaria, and HIV which all come with their own medical complications [45]. Cocaine ingested via other means comes with medical complications related to cardiac and neurological issues that are attributed to the substance

itself. This can result in strokes and cardiac arrhythmias which can cause sudden death [45]. Cardiac related issues have also been shown to arise with the use of methamphetamines and prescription stimulants that can result in death [45]. There are several other medical complications that are caused by using substances which accelerate death, the ones listed here are just a few examples. Medical complications that result in or hasten death is only one way in which death can be accelerated by this ISDB.

Several studies have shown that unintentional overdose and deaths resulting from motor vehicle accidents are prevalent ways this ISDB can be fatal. Currently, poisoning resulting from drugs is the leading cause of unintentional death in adult Americans. Prescription opioid use is especially likely to result in poisoning and has been shown to be responsible for almost half of drug overdose deaths [43]. Heroin, cocaine, and methamphetamines have also been shown to result in fatal overdose and contribute alongside opioid use to overdose being the leading cause of unintentional death in the United States [46]. Alongside unintentional overdose, many substances including alcohol, cannabis, methamphetamines, cocaine, and opioids have all been shown to be associated with fatal motor vehicle accidents [39]. Research also indicates that the combined use of substances may result in an additional risk of injurious motor vehicle accidents. The discussed mechanisms associated with various substance use that hasten or lead to death align with the established literature that prolonged and abusive use of substances is associated with heightened mortality rates [40, 41]. The adverse effects from the ISDB of substance use are clear, but these consequences do not account for their development.

There are several notable risk factors commonly associated with the use of substances as an ISDB. The presence of a comorbid mood or anxiety disorder has been found in multiple studies to occur at increased rates with substance use disorders [47, 48]. Research conducted using DSM-IV criteria found that the strongest associations and frequencies of comorbidity were between illicit drug use disorder and major depression. This was followed by illicit drug use disorder and any anxiety disorder, AUD and major depression, and AUD and any anxiety disorder [48]. Depression has been extensively researched in relation to SUDs and has been found to be a notable risk factor for their future development [49]. Adolescents have been found to be a population that is particularly at risk for the development of an SUD. Within this group there are several risk factors that have been identified that may further increase risk of SUDs developing such as psychological dysregulation, a PTSD diagnosis, and parental history of substance abuse as well as various trauma related experiences such as sexual assault, physical assault, or bearing witness to violence [50, 51]. In adolescence, factors specifically related to environment or upbringing are also noted to influence the development of SUDs, such as overall family functioning, peer influence, and parenting practices [51]. Theoretical understandings related to the risks associated with the development of SUDs and the adverse effects associated with this ISDB have informed treatment practices that have found to be beneficial in reducing or ceasing usage.

Life satisfaction and overall well-being have been shown to be negatively associated with the chronic or abusive use of various substances in adolescents

and college aged individuals. While there are many theories that attempt to explain these findings, one prominent explanation is that substances are being used to maladaptively cope with psychological pain and distress [52]. This is informed by theory related to substances being used as means to cope with negative effects of mood disorders which is further supported by the frequency of comorbidity found between mood disorders and SUDs [49]. There are several options available for the treatment of various substance use disorders that are thoroughly researched and efficacious including motivational interviewing, CBT, and couples' treatments [53–55]. CBT protocols can be highly varied but tend to include a few key components of treatment, including a focus on cognitions, behaviors, motivation, and skills training [54]. Skills training includes the building of emotion regulation skills such as distress tolerance and coping skills, which is an aspect of treatment that is particularly beneficial for those who may be engaging in substance use as a means of maladaptively coping with negative emotions [54]. In conjunction with the other major components of CBT, engagement in the ISDB of substance use can be effectively reduced or abstained from.

Recklessness and Impulsive Behaviors

Reckless and impulsive behaviors (RIBs) are unique among ISDBs in that they can be a contributing factor to other ISDBs or can be defined separately as their own category. One reason for this is that the act of engaging in risky/reckless or impulsive behaviors is part of diagnostic conceptualizations involving trauma, personality, and addictive disorders which can contribute to self-destructive behaviors [17]. Some ISDBs, however, such as substance abuse and eating disorders, both carry a specific risk of harm to the individual, as well as documented difficulty with impulse control [56]. So, while RIBs can be a contributing factor to some ISDBs, there are also several more overt forms that may directly result in permanent harm and hasten death. It should be noted that while there is overlap between risk, recklessness, and impulsivity, they are seen as distinct in the literature, even if they are addressed under a single umbrella term in regard to ISDBs. Arnett [57] differentiates risky behavior as socially acceptable thrill-seeking or other behaviors with limited consequences, in comparison to recklessness which he described as acting without precautions to obvious and avoidable danger. It is acknowledged by Arnett however that there is a lot of overlap between the two, and in the literature it is often interchangeable [17, 58–60].

Similarly, according to Moeller et al. [61] impulsivity has not been clearly defined in the literature, despite being present in a variety of DSM diagnoses. Hamilton et al. [62] described impulsivity as a “predisposition toward rapid, unplanned reactions to internal or external stimuli with diminished regard to the negative consequences of these reactions to the impulsive individual or to others.” With the scope and variability in these terms, identifying and defining exact prevalence rates for these behaviors can be a challenge. RIBs can vary widely in presentation, prevalence, and can contribute to many potential risks for harm, and as such not every form of this

ISDB can be discussed. A few key examples however, such as engaging in dangerous driving, as well as behavioral addictions such as gambling, all carry the danger of causing permanent harm to self or others.

Vehicular injury is currently the leading cause of death for young adults aged 15–24, the second-most leading cause of death for adults aged 25–44, and is also one of the most likely causes of non-fatal serious injury to adults across age ranges [63]. Reckless driving for young adults has been estimated to contribute significantly to these vehicular mortality rates [64]. In 2018 the National Highway Traffic Safety Administration found that more than 30% of fatal accidents were caused by speeding, driving under the influence, or driving carelessly [65]. The risk of death and the risk of lifelong complications due to serious injury are clear consequences of these behaviors. Long-term physical injury, medical complications, loss of functioning, psychological trauma, and harm to others are all potential adverse outcomes for those who may engage in this form of ISDB. Impulse-control disorders as well as behavioral addictions such as gambling disorder are another facet of this ISDB, having been shown to cause major economic and psychological harm and have a direct link to impulse control difficulties [66]. Research has shown that a condition like problematic gambling can harm financial stability, emotional or psychological well-being, physical health, career success, and can even lead to increased substance use, criminal activity, or more widespread community harm [66–68].

Several different risk factors have been found that might contribute to reckless behaviors, with age and gender having been found to be highly associated with reckless driving [69]. While the risk of reckless driving was highest with young men, several other psychosocial factors were found to influence recklessness while driving [70–72]. McNally and Bradley [71] used exploratory factor analysis to find that among young drivers there were four distinct categories of reckless driving: distracted driving, driving under the influence, driving a vehicle beyond its design expectations, and dangerous positioning in relation to other vehicles. Sarma et al. [72] found that social and environmental factors such as attitudes toward speeding, perceived control, and positive social reinforcement all played a role in reckless behavior. While other literature has also found strong correlations with sensation seeking behaviors, under-developed threat assessment, aggressive behavior, and personality characteristics as associated risks for developing the ISDB of reckless driving behavior [57–59]. Luk et al. [70] also found that impulsivity had a significant interactive effect on many forms of reckless driving and that it may consistently influence risky driving with high-risk young adults.

Risk factors for gambling disorder had similar age and gender risk factors to those found in reckless driving, with men ages 18–24 being at the highest risk for gambling disorders [73, 74]. In addition to age and gender risk factors, substance use, low socioeconomic status, identifying as a minority, and access to a variety of options for gambling were all significant risk factors in developing problematic gambling. The literature emphasized how impulsivity needs to be assessed through a multidimensional framework due to the variety of associated risks [73, 75]. Although substance use has been suggested as a cause for developing impulsivity issues seen in problematic gambling, research has found impulsivity

is a risk factor found in both substance use and gambling independent of one another [76]. Other psychological disorders that have central elements of impulse-control issues were also highly co-morbid with gambling [77].

The danger of serious physical harm due to risky driving, substance use, or sexual practices, and the risk of serious economic, social, legal, and psychological harm caused by impulse control disorders and behavioral addictions show how impulsivity and recklessness as an ISDB can cause serious personal harm [56]. Treatment for reckless and impulsive behaviors, however, tends to address specific conditions that include these behaviors rather than addressing them individually. There are well-established therapies for disorders such as ADHD, PTSD, impulse-control, and addictive disorders that all incorporate strategies for managing the reckless and/or impulsive aspects of these conditions. Moeller et al. [61] found that there was strong evidence for deficits in problem-solving and emotion coping strategies in populations with impulse issues. Therapies such as CBT and DBT were both found to be efficacious in developing problem-solving, emotion regulation, and distress tolerance skills, as well as reducing overall levels of impulsivity [61]. CBT or related therapies such as DBT and CPT were found to be efficacious in treating a number of other conditions that have RIBs including gambling disorders, ADHD, and substance use disorders [61, 78]. In addition, because reckless behaviors are more common in younger age groups, family-focused therapies were tested and shown to be as effective or even more effective in treating adolescent substance use and risk-taking behavior [79].

Self-Neglect

While older adults still engage in other previously discussed ISDBs, acts of self-neglect are especially salient for this community. Elder self-neglect is a global health issue that may result in more deaths than direct methods of ending one's life [80]. Self-neglect is a broad term in which there is little consensus on an exact definition. Some definitions of the term include behaviors such as failure or refusal to provide oneself adequate shelter, food, water, medications, personal hygiene, and compliance with needed medical treatments [80, 81]. Exact rates of prevalence can be difficult to identify due to methodological inconsistencies related to varying operational definitions, but within a community population sample of Chinese older adults in Chicago, the rate of self-neglect was found to be 29.11% [82]. Similarly, 22.8% of South Korean older adults who lived alone were found to have been engaging in some form of self-neglect [83]. As self-neglect is relatively common, wide in scope, and severely destructive to one's life to the point of ultimately hastening and indirectly resulting in death, specific acts within this ISDB will be reviewed.

A common form of self-neglect in older adults is medication nonadherence, which is a term that describes medication-taking behaviors that do not align with the prescribed regimen [84]. Older adults take more medications than individuals from other age groups on average, and about 50% of them are

nonadherent [85]. Nonadherence to medications has been associated with worse patient outcomes, reduced functioning, increased mortality, and an exacerbation of disease severity [86, 87]. Additionally, medication nonadherence has been shown to explain one-fourth of admissions to nursing homes, one-fifth of preventable negative drug effects in a community sample, and one-tenth of medical emergency admissions in older adults [88]. As medication nonadherence directly influences the illness the medication was prescribed to treat, failure to properly adhere to medication regimens primarily results in medical complications which can lead to death.

Medication nonadherence is one common way self-neglect arises as an ISDB, but other detrimental acts such as refusal to provide oneself with food, water, or shelter are also frequently seen. These acts are under-researched as an ISDB in comparison to nonadherence to medications or treatment recommendations but come with a plethora of medical repercussions that can lead to death. Nelson and Farberow [89] reported that in a sample of older men who were engaging in various ISDBs, 43.7% displayed injurious eating behaviors. These findings are supported as self-starvation has been found to be the most frequent ISDB method used among institutionalized older adults [90]. Starvation leads to several medical complications that result in and hastens death including cardiac wasting and arrhythmias [19]. The ISDB of self-neglect is devastatingly harmful, but exactly how engagement in self-neglect is developed is not clear. Despite this, some associations have been identified that increase the likelihood of self-neglect being engaged in.

A notable risk factor for self-neglect in older adults is psychological distress and depressive symptoms [91]. Associations between depressive symptoms and self-neglect reports made to Adult Protective Services were found in a study on older adults [92]. In South Korea older adults who were engaging in ISDBs of self-neglect were also found to have higher levels of depression symptoms [83]. Researchers also found social support to be an important factor regarding risk of engaging in an ISDB of self-neglect. In South Korea older adults lack of familial support was identified as a risk factor for self-neglectful behaviors [83]. Similarly, older adults who had fewer social engagements or who had smaller social networks were found to be more likely to self-neglect [93]. Additionally, socioeconomic status is a potential risk factor for self-neglect, but research varies as to its level of significance. Some researchers have found that higher SES is associated with a lower frequency of self-neglect, while others have not found this factor to be significant [83, 94]. The greater the number of medications within an older adult's regimen was also found to be associated with the risk of medication nonadherence as an ISDB of self-neglect. In addition, level of physical functioning was identified as risk factor for medication nonadherence [95]. This may suggest that factors outside of self-neglect related behaviors are of specific interest when it comes to medication nonadherence. Future research is needed on the specific associated risks of engaging in the ISDB of self-neglect as answers may illuminate additional ways of prevention.

As with other ISDBs, engagement in self-neglect, including medication nonadherence and refusal of food, were found to be associated with lower quality of life scores. This held true across four domains, including psychological health, physical health, social relationships, and the individual's environment [96]. Treatment to

combat this for the ISDB of self-neglect takes many forms, but in general is focused more on assessing that self-neglect is occurring rather than specific psychological interventions. Given the elusive nature of self-neglect and the covertness of the many behaviors that fall within this concept, assessing whether an older adult is engaging in some of these behaviors is critical. A network of caretakers, doctors, nurses, therapists, communities of faith, and other individuals or systems with which the older adult regularly interacts should be observant to potential signs of self-neglect. This allows for a multidisciplinary and multi-perspective way to assess for issues related to shelter, food, water, medication adherence, hygiene, and treatment adherence in older adults [91]. Assessments can then help various providers take the steps needed to prioritize the older adults' immediate needs and seek out useful resources [97].

Additionally, as depressive symptoms are a risk factor for engaging in self-neglectful behaviors, and symptoms may be present as behaviors are being engaged in, treatment centered on alleviating these symptoms is advisable [92]. CBT and reminiscence therapy have been found to be well-established treatment options for combating depression in older adults [98]. Complex medication regimens that are associated with medication nonadherence, and have been identified as a notable risk factor, should be addressed if applicable. Physicians may need to focus on medication reconciliation to alleviate the complexity of taking multiple medications [99]. Generally, self-neglect is a particularly difficult to assess ISDB, but as it is extremely detrimental to older adults who engage in the many behaviors encompassed within the term it is important that it is better understood by those who can take steps to mitigate or prevent its negative effects that can ultimately lead to death.

Conclusions

In sum, an indirect self-destructive behavior is a term used to describe a wide range of actions that a person might take that could lead to death when continuously engaged in, but that are not overt or direct acts that lead to loss of life. These behaviors are difficult to quantify because they may present outside of what is typically considered within a clinician's assessment of suicide risk, may be behaviors that often co-occur with other disorders, or the characteristic problems of a diagnosis may overshadow the death hastening features of the engaged in behavior. Understanding in greater detail the common forms these behaviors arise as, their prevalence, how death is hastened, risk, and treatment is important to fully conceptualize the client's needs. While these behaviors may not always be seen regarding their risk of death to self, they are crucial because they represent an under-researched area of long-term, lasting harm. This aspect of these behaviors not only represents an unaddressed need of the patient but can lead to more detrimental outcomes if not treated. It is because the death hastening aspect of these behaviors are ordinarily overlooked that a greater attention to associations of risk, assessment, and treatment is necessary. Clinicians often forget that ISDBs are along the suicide spectrum and pose a real risk of death to their clients. This is especially true considering how the engagement in ISDBs may increase risk of overt suicidal behavior.

Abstract

This chapter proposes a two-axis approach of human development to the problem of preventing suicide across the life span (i.e., individuation-deindividuation and attachment-detachment). We apply this thinking to the Eriksonian model of consecutive life stages. Typical interpretations of Erikson suggest healthy development is achieved by resolving the crisis at each of his life stages *horizontally* in favor of the *syntonic* as opposed to the *dystonic* ego quality of that stage (e.g., trust instead of mistrust). Our two-axis view, in contrast, suggests that each stage is entered at the *dystonic* position (e.g., mistrust) and must be worked through *vertically* to achieve *syntonicity* (e.g., trust) necessary to move ahead successfully to the next advanced life stage. Successful development involves forward regression to the next life stage (temporarily moving backward in position to move forward in stage). In contrast to this successful congruent developmental advance is potential suicidal crisis engendered by an incongruent resolution of the individuation-attachment challenge at each life stage. This is accentuated by premature pressures to force an individual ahead to a more advanced life stage that he/she may not yet be able to cope with.

Introduction

This chapter proposes a two-axis approach of human development to the problem of preventing suicide across the life span (i.e., individuation-deindividuation and attachment-detachment). We apply this thinking to the Eriksonian model of consecutive life stages. Typical interpretations of Erikson suggest healthy development is achieved by resolving the crisis at each of his life stages *horizontally* in favor of the *syntonic* as opposed to the *dystonic* ego quality of that stage (e.g., trust instead of mistrust). Our two-axis view, in contrast, suggests that each stage is entered at the *dystonic* position (e.g., mistrust) and must be worked through *vertically* to achieve *syntonicity* (e.g., trust) necessary to move ahead successfully to the next advanced life stage. Successful development involves forward regression to the next life stage

(temporarily moving backward in position to move forward in stage). In contrast to this successful congruent developmental advance is potential suicidal crisis engendered by an incongruent resolution of the individuation-attachment challenge at each life stage. This is accentuated by premature pressures to force an individual ahead to a more advanced life stage that he/she may not yet be able to cope with.

The paradigmatic life-promoting biblical stories of Elijah, Job, David, Moses, Jonah Rebecca, and Ruth are contrasted in this regard to the matching suicidal Greek and Roman stories of Ajax, Zeno, Coriolanus, Oedipus, Narcissus, Phaedra, and Antigone.

Even an experienced clinician may become apprehensive when faced with a potentially suicidal patient. Some of this apprehension is undoubtedly functional in evoking appropriately increased caution in the treatment approach. However, such nervousness may also lead the clinician to shy away from and indeed stigmatize the patient, seeing him as somehow removed from normal developmental issues of life. To be sure, the clinician working with a suicidal patient must be cognizant of the life and death issues unique to that patient. However, it is important that this be done in a way that places the suicidal crisis within the context of human development. Developmental stage theories have suggested that there is a general tendency for people to face certain issues at specific life stages. What may represent a suicidal risk for an adolescent may be a quite normal life challenge for an older adult and vice-versa. "Failure to survive" may manifest itself differentially across the life span. It may be quite instructive to compare matching biblical and Graeco-Roman narratives in this regard. Why are there so many suicides in the Greek and Roman narratives and so few in corresponding biblical narratives facing the same life stressors?

Perhaps the best known of developmental stage theories has been developed by Erik Erikson. Erikson describes eight different stages of life, each presenting its own psychosocial crisis. Later in this chapter we will present a taxonomy of these stage-specific crises. If the crisis is satisfactorily resolved, a positive quality is added to the ego. If it is unsatisfactorily resolved, a negative factor is added. For example, the crisis at infancy between the infant's physiological needs (hunger, contact, etc.) and caregivers' response leads to the acquisition of the positive ego quality of *basic trust*,

Fig. 1 Bidimensional distancing and Transactional analysis (Kaplan et al. 1984, p. 118). Note: The letters and wording in the quadrants have been changed in Fig. 1, and they thus differ from the presentation in the 1984 Kaplan, Capace, & Clyde article in the 1971 Ernst OK Corral

or to the negative quality of *basic mistrust*. The toddler facing fecal embarrassment develops shame or autonomy; the play age child develops guilt or initiative. Later stages are discussed in depth below [1–4].

A Two-Axis Model of Healthy Development Versus Pathological Fixation

It is the thesis of this chapter that pushing an individual to move to a more advanced stage before he/she has satisfactorily resolved the earlier stage can lead to a developmental crisis, sometimes suicidal in nature [5]. In contrast, the present chapter builds on a two-axis stage approach to human development that has been proposed by Kaplan and his colleagues. The essence of this approach is to divide interpersonal distance into two axes: *individuation-deindividuation* and *attachment-detachment*. Figure 1 presents this in a quadrant using the terms of transactional analysis of what has been labelled the OK Corral [6–10].

Individuationdeindividuation is designated by internal circle icons or *boundaries* and differentiated as the full capacity to differentiate (represented by a dark-line circle), semi-capacity to differentiate (represented by a light-line circle), or no capacity to differentiate (represented by a broken-line circle) from these same external objects. *Attachment-detachment* is designated by external square icons or *walls* and defined as the full capacity to bond with others (represented by a broken-line square), semi-capacity to bond (represented by a light-line square), or no capacity to bond to others (represented by a dark-line square). This is illustrated in Table 1.

Figures 2 and 3 differentiate healthy development from clinical fixation and self-destructive attempts to break out of it.

Bidimensionalizing Erikson

Healthy development is achieved by resolving each stage crisis *horizontally* in favor of the positive or syntonetic as opposed the dystonic ego quality. My two-axis view of Eriksonian stages proposes that an individual is propelled by a life event (e.g., weaning) into the negative or dystonic position (e.g., mistrust) and must move

Table 1 Icons representing capacity regarding external objects

Attachment/Detachment	Individuation/Deindividuation
 Full Capacity to Bond	 Full Capacity to Differentiate
 Semi-Capacity to Bond	 Semi-Capacity to Differentiate
 No Capacity to Bond	 No Capacity to Differentiate

Fig. 3 Clinical fixation

ahead *vertically* to achieve the positive syntonc quality (e.g., trust) and to attain a stage-specific syntonc equilibrium. In turn, a subsequent life event or stressor (e.g., toilet training) *forwardly regresses* the individual into a new dystonicity (e.g., shame) with regard to the now-broader social radius, parental persons. *In other*

words, what I am suggesting is that successful development involves not the avoidance of the negative or dystonic ego qualities at each stage but the very plunging into each of them as the natural sequela of the preceding life event. Successful development involves working through a stage vertically to attain the respective stage-specific positive or syntonic ego position, followed by *forward regression* to the next advanced stage.

The term *forward regression* is applied to this simultaneous regression in level (e.g., trust to shame,) in an advance to the next stage, where the within-stage process from dystonic to syntonic ego quality must be once more worked through. Thus a toddler who has mastered his home environment will likely forwardly regress to a more tentative coping style when he first enters preschool.

The purpose of this approach is to provide the working clinician with a set of guidelines to distinguish at each life stage an individual undergoing healthy stage-appropriate development from one clinically fixated. A life event introducing a more advanced stage life should impact on these two individuals in very different ways. The life event may be a quite normal stressor and even represent an invigorating challenge for the healthily developing individual, but a potential suicidal trigger for the clinically fixated individual. The working clinician may support, encourage, and even facilitate the event for the first type of individual but attempt to delay or even prevent the event for the second type of individual.

Within-Stage Dynamics

We have differentiated developmental and clinical axes above: a developmental B- > E- > D axis (Fig. 2) and a clinical A<->C axis (Fig. 3). Let us consider the developmental B- > E- > D axis first.

Cell B represents an individual confronted with a stressor who becomes temporarily disoriented. He can be described as deindividuated and detached. He by definition is immature and needs to defend himself. So he constructs a wall around himself. *Deindividuation* (represented by a broken-line circle) represents a low state of individual organization and definition, and *detachment* (represented by a dark-line square) can be thought of as defensive in structure. An impermeable wall is necessary to shield the inarticulately defined individual from external engulfment.

In Cell E, the individual is slowly maturing out of his disorientation and can be described as semi-individuated and semi-attached. A modicum of self-definition has been achieved, a semi-articulated boundary (light-line circle), but some defensive structure is still necessary, a semi-permeable wall.

In Cell D, the individual has fully adjusted to the stressor and can be described as fully individuated (dark-line circle) and attached. Here the defensive structure can be quite minimal, a permeable wall (broken-line square) as there is little danger of external engulfment.

The logic of this developmental axis is simply that the loosening of one's defenses (i.e., greater permeability of walls) should occur in conjunction with the strengthening of one's ego (i.e., greater definition of boundaries). The specific manifestations

of each of these positions should vary with the stage; however, their general form should remain invariant. Healthy development at each stage requires an ongoing *congruency* between individuation and attachment. Pathological development, in contrast, manifests as fixation on or continuous oscillation between individuation and attachment. (Kegan, in contrast, seems to outline the spiraling, alternating, or oscillating view of expression of these two forces as indicative of normal development [11, p. 108].) Specifically, we see it as reflecting *incongruent* resolution of the individuation-attachment dilemma, i.e., imbalanced movement from B to either A or C. What makes this A-C axis clinical (Fig. 1b) is the bad fit and lack of coordination between walls and boundaries.

The A individual attempts to become attached to the external world before achieving individuation, resulting in what we call *enmeshment*-loosening defenses (permeable walls, represented by broken-line square) while the ego is still ill-defined (unarticulated boundaries, represented by broken-line circle). The C individual, in contrast, is *disengaged*-remaining detached even after becoming sufficiently individuated-holding onto defenses (impermeable walls, dark-line square) even after the ego has become sharply defined (articulated boundaries, dark-line circle). The A/C individual is split between these contradictory tendencies, oscillating unstably between these two styles.

To help the individual escape the A-C clinical axis and begin to develop integrated individuation and attachment, the therapist must facilitate backward regression to the B-level in the same stage. From this position, the B->E->D journey may be traversed, preparing the individual for healthy forward regression to the next stage.

Between-Stage Dynamics

It is this point of transition between stages that challenges the individual to achieve healthy integration or suffer suicidal disintegration. These two alternatives are portrayed respectively in Fig. 3a and b. In each figure, the life event is portrayed as a “tube” leading from the D level at Stage (i) to the B level at Stage (i + 1). Non-suicidal integrations (Fig. 2a) are indicated by healthy developmental progression from Level (B) to Level (E) to Level (D) within a specific stage. Each successive stage must be entered at Level (B). In other words, “progression in stage” is achieved through “regression in level” and is precipitated by the specific *life event* initiating the next stage. Here the stance of the therapist should be to facilitate or encourage the life event that precipitates the next stage- Level $B_{(i+1)}$ that *forwardly regresses* the individual from D_i to $B_{(i+1)}$. Although the individual may experience a temporary adjustment reaction (B) upon entering a new stage, he will recover his/her equilibrium (E) and ultimately will flourish (D).

On the other hand, suicidal disintegrations are indicated by clinical fixation on the A-C axis. Such enmeshed-disengaged behaviors indicate that the individual may be unready for Level $B_{(i+1)}$. Although an individual might have stabilized in the A (enmeshed) or C (disengaged) positions within a stage, the demands of $LE(i + t)$

may actually prompt an A-C individual at Stage (i) to attempt an A/C_i (borderline or even psychotic) resolution. This may present as a pseudo-D (pseudo-mature) position, which may serve to mask pathology both to self and to others. However, it does not represent any true integration between individuation and attachment, and may even deepen the disintegrative process as it disguises it. Extreme distress can result from the attempt to *simultaneously* apply A and C styles, creating a potentially explosive level of stress as the individual tries to resolve the apparently irreconcilable opposites to cope with the unaccustomed challenges of the new life stage. The outcome of this crisis might be that the pressure of this inadequate coping style would propel the individual through the life event into the next stage on the A-C axis, if not into a suicidal disintegration. Here, the therapist must attempt to delay the life event, or to protect the individual from its effects as much as possible, while facilitating backward regression to the same-stage B level. From this position, healthy development of integrated individuation and attachment may be achieved, allowing normal forward regression to the next stage. The difference between these two axes is portrayed in Fig. 4.

Table 2 summarizes this process at each stage, listing the premature life events as triggering events and the resultant A/C reactions as suicidal behaviors. In such a situation, the stance of the therapist should be to delay life event ($i+1$) or protect the individual from its effects until the individual indicates readiness for it in terms of showing healthy resolution on the $B \rightarrow E \rightarrow D$ developmental axis.

While the pattern of development described above applies to infants, toddlers, and play age children, suicide is a rare occurrence in young children. These stages are therefore omitted from Table 1 and are not discussed in this chapter which begins at Stage 4: School Age. It should be noted, however, that failure to achieve healthy integration of attachment and individuation at the earliest stages may set a pattern of

Fig. 4 Healthy development versus clinical disintegration

Table 2 Non-suicidal integration versus suicidal disintegration at each life stage

Non-Suicidal Integration					
Stage/Age (Social Radius)	Psychological Risk Factors	Integrative Non-Suicidal Resolution	Core Strength	Normal Life Event	Forward Regression to Next Stage

A-C behavior that can set the stage for a suicidal crisis later in life. The contrast between healthy development and clinical pathology is illustrated in Fig. 5.

Stage 4 – School Age: From Inferiority to Industry

Stage 4 denotes Erikson's school age (approximately ages 6–12). It is precipitated by the life event of *social evaluation*. The social radius has broadened for the child from *nuclear family* to *school and neighborhood peers* (SR₄). According to Barker and Wright, about 50% of the school-age child's interactions are with other children as opposed to only 10% in this regard for 2-year-olds [12]. The demands of social evaluation forwardly regress the previously syntonic *initiating* (D₃) play-age child into an initially dystonic stage of *inferiority* (B₄). Criticism from peers and negative social comparison can lead to a pessimistic self-definition with regard to future success and even a sense of "learned helplessness" and depression [13]. Withdrawal from social interaction (detachment) accompanies the self-doubt (deindividuation) for the B₄ child and may well provide a protective shield until the child begins to feel better about exposing (permeable wall) his abilities (articulated boundary).

Healthy Developmental Integration

The core strength behind healthy advance along the B->E->D developmental axis is Erikson's *competence*, and the major process is education. The child is exposed to a range of disciplines and to the language of concepts that allow him or her both to organize his or her experiences and acquire new skills. Children must be helped to set realistic goals for themselves to enable them to experience at least some success. Each child is unique in response to critical evaluation. It may be traumatizing for some, yet for others it may be quite helpful in his developmental journey. With difficult tasks, a child's concentration and indeed persistence may be hampered by external evaluation. Under more relaxed conditions, however, outside evaluation can be helpful in helping the child remain on target and improve his performance. Individuation and attachment are inextricably linked in healthy development. The more secure a child feels, the more he can let down his guard and relate to his peers.

Pellegrini, for example, has shown that children who display maturity in their social reasoning (individuation) are likely to be more positively evaluated by their peers (attachment) [14]. The strength of a healthy child's (D₄) need for success is well established by the end of the school-age stage. These are also the years when children can have "best friends," a process Sullivan argues is crucial for later heterosexual relations.

A child showing D₄ industry behaviors is ready to face the life event of adolescence (LE₅) of *appropriate social identity demands*. Should such a child appear in the clinic, the therapist can safely facilitate this process. The child will *forwardly regress* through meeting these demands to the B₅ state of normal *identity confusion* characteristics of the early part of adolescence.

Potentially Suicidal Disintegration

There are many pitfalls along this developmental journey, however. Calhoun and Morse, for example, have shown that failure in school and the experience of public ridicule can interact with an initially negative self-concept to cause long-lasting damage to a child's self-esteem [15]. The core pathology for Erikson at this stage is *inertia* which can be expressed either in A or C pathologies.

One type of A₄ pathology is *hyperactivity*; the hyperactive child is unable to control his/her impulses (insufficiently articulated boundaries), and Stewart estimated that hyperactive children represented some 4% of the grade school population in the United States [16] in 1967. Another form of the A₄ (deindividuated attachment) structure can be labelled *conformity*. Children learn to dress and talk in ways that gain peer approval, in extreme cases showing willingness to go along with antisocial peer behavior. This has manifested itself over the years in tragic incidents at our schools.

Costanzo, for example, has shown that late childhood/early adolescence represents a peak period of conformity [17]. The A₄ child is quite simply afraid to be different lest he or she receive negative social evaluation. Thus he blends in (deindividuates) to avoid the evaluation process. The child may accomplish the same goal through going to the opposite polarity, a C₄ (detachment individuation) structure. This can be labelled *peer rejection* with associated feelings of loneliness. The direction of this process is not always clear. Sometimes the C₄ child may reject (detach) to avoid being rejected. However, the result for the child can be similar – loneliness.

A significant proportion of children in this study felt left out, had trouble making friends, and felt that they were alone. Furthermore, children who are rejected tend to be disruptive and aggressive with peers and often require psychiatric treatment in adolescence or adulthood. Though Robins cautions us that “most antisocial children do not become antisocial adults,” there is no question that the clinical conformity-peer rejection axis is problematic for the school-age child [18, p. 611]. Significantly, these A and C polarities are reflected in suicidal behavior as well. At least two studies have shown depression is more prevalent among suicidal than non-suicidal children [19]. Depression among children may be manifested by both A and C behaviors. A₄ manifestations include increased anxiety while C₄ manifestations include antisocial behavior and aggression. One study finds that school-age children who contemplate suicide are likely to be depressed and to dislike themselves (A₄). Another study points to suicidal children of a second type; they are angry, assaultive, and tend to approach problems in an assaultive C₄ manner [19].

A child exhibiting these A-C behaviors is not ready for the precipitating life event of adolescence and the therapist must attempt to delay this event or protect the child from it as much as possible. If she or he fails, the *premature demands of social identity* may well trigger an A/C suicidal crisis. Here the A/C₄ child may show signs of *both depression and aggression* in an attempt to simulate *pseudo-industry* and may even be at greater risk for suicide than before.

Stage 5 – Adolescence: From Identity Confusion to Identity

Stage 5 in our model describes Erikson's very important adolescent stage (approximately ages 12–22). It is initiated by the life event of *social identity demands* (LE₅) that forwardly regresses the syntonically *industrious* D₄ school age child into an initial dystonic position of *normal identity confusion* (B₅). A child may well present clinically with an adjustment reaction. The social radius at this stage is *peer groups and outgroups* (SR₅). The life task is to find what groups to join and what groups to avoid. The adolescent may experience a sense of narcissistic grandiosity with the resultant lack of ability to commit to any particular group. This stage has been studied at length by Marcia [20] and by Bourne [21] among others and describes the process by which an adolescent matures to the point of being able to achieve a social identity allowing him to make a realistic social commitment.

Healthy Developmental Integration

The core strength for Erikson at Stage 5 is *fidelity*, which is realized through the integrated achievement of both individuation (Marcia's exploration) and attachment (Marcia's commitment). A successful integrated progression along the developmental B->E->D axis with regard to both of these life issues leads to a syntonik position of *identity achievement* (D₅) which, for Marcia, involves an individual who has undergone exploration and made commitments. A number of studies have shown that such individuals do well on a number of achievement and interpersonal indicators.

A child showing D₅ identity behaviors is ready to face the life event of young adulthood (LE₆)-*appropriate personal identity demands*. The therapist should try to facilitate this process. The adolescent will forwardly regress as a function of meeting these demands to the B₆ stage of normal *isolation* characteristic of the early part of adolescence.

Potentially Suicidal Disintegration

The core pathology at this stage has been described by Erikson as *repudiation*, which can lead to fixation and oscillation on the clinical AC axis expressed either in what Stierlin has called "expelling" (adolescents pushed by their families into premature autonomy) or "binding" (adolescents infantilized by their families) [22]. Such adolescents may present with a DSM5 classification of either as a Separation Anxiety Disorder (309.21) or a Cs Avoidant Disorder of Childhood or Adolescence (313.21). Depression represents the clearest example of A₅ behavior and is the most common pathological symptom of suicidal individuals of all ages. The depressed adolescent who has suicidal thoughts is greatly at risk for suicide [23]. The work of Shaffer [24] highlights the prevalence of depressive symptoms among adolescent suicide attempters and adolescent suicide completers. Garfinkel et al. [25] report a

positive correlation between level of depression and lethality of suicide attempts among 505 adolescents admitted to a hospital emergency room for suicide attempts.

The importance of depression in adolescent suicide attempts has also emerged in many studies [26], including those of Robbins and Alessi, Pfeffer et al., and Borst, Noam, and Bartok. The C_5 polarity may also be a factor in suicidal behavior, whether expressed in pathological social isolation or antisocial behaviors.

Other studies have pointed to the role of social isolation in adolescent suicide. Contributing to this sense of social isolation is the pervasiveness of high degree of family mobility. In the past, the highest degree of suicide occurs in the Western region of the United States which also represented the highest degree of family relocation. The lowest incidence of suicide occurred in the Northwest which has the lowest degree of family relocation. Topol and Resnikoff have pointed to the role of social isolation in youth suicide [27]. They observe that many adolescent suicides have had a history of difficulty in relating to peers. They rarely have close friends and are “nonjoiners” who are often invisible to peers and teachers. A significant number of suicidal adolescents who are not depressed present with either a *conduct disorder* (312.89) or *antisocial personality disorder* (301.7), both representative of a C_5 position.

A child exhibiting these A-C depressive-aggressive behaviors is not ready for the precipitating life event (LE_6) of young adulthood-appropriate personal identity demands, and the therapist should consider attempting to delay this event to protect the child from it as much as possible. If he fails, the *premature demands of social identity* may well trigger an A/C suicidal crisis. Here the (A/C) $_5$ borderline child may show signs of both depression and aggression in an attempt to simulate a *pseudo-identity* and may even be at greater risk for suicide than before. Indeed, this is exactly the finding emerging from the previously discussed work of Borst, Noam, and Bartok, who report that the majority of suicidal adolescents in their study were diagnosed with a mixed (A/C) $_5$ *conduct-affective disorder*.

The conduct disorders in their sample have a much lower incidence of suicide than do the affective disorders, leading Borst, Noam, and Bartok to warn against the suicidal risk inherent in premature development. They suggest that “the self-protective and externalizing qualities of the earlier developmental positions put a person at greater risk for impulsivity, acting-out, or delinquency but may shield the adolescent from directing the aggression against the self, as the problem is viewed as mainly externally located.” This squares with findings of Brent et al., indicating that completed adolescent suicides were more likely to evidence a bipolar disorder or a major affective disorder with comorbidity than adolescents hospitalized with suicidal behavior [28].

Stage 6 – Early Adulthood: From Isolation to Intimacy

Stage 6 in our model describes Erikson’s early adulthood (approximately ages 22–34) with a social radius of *partners in friendship and sex* (SR_6). It is initiated by Life Event 6 – *personal identity demands* – which forwardly regresses a

previously syntonic *identity-achieving* adolescent (D₅) into a dystonic state of *normal isolation* (B₆). The hard-won social identity emerging from group commitment and membership is no longer enough and the individual may present with a normal sense of isolation.

The young adult requires a more developed personal identity but must first free himself from the intense peer pressures emerging from his preceding social radius. This confusion in his or her personal identity (deindividuation) may result in a sense of loneliness and isolation (detachment). According to Marcia, this journey involves the process of both exploration (what we mean by individuation) and commitment (what we mean by attachment). This dystonic first level (B₆) represents a deficiency in both individuation and attachment, and seems to correspond to what Marcia has labelled *moratorium*. Individuals in this moratorium or identity-confusion state have not proceeded very far into exploration (deindividuation) nor have they made any real commitments (detachment).

Healthy Developmental Integration

Erikson has labelled the core strength at this stage *love*, which in Buber's sense allows the formation of one's own identity and respect for that of the other (in other words, an I-thou relationship) essential to any genuine syntonic *intimacy* (D₆). Central to this journey is the establishment of a self separate from one's parents on which one can base one's own life. Peers have served the adolescent well in facilitating this separation process. But now the young adult must turn to more intimate dyadic encounters *to* further develop this separation. This process has been studied by a number of researchers, some focusing on the movement from high school to college, others looking at the development from childhood to adulthood. Regarding healthy development on the B->E->D axis, Katz et al. discovered that healthy young adults learned to make decisions without seeking permission from their parents and moved toward closer relationships and assumption of the marital role [28]. Vaillant found that the "best outcome" younger adults tended to be well-integrated and practical in late adolescence and early adulthood, and the "worst outcome" young adults asocial [29]. Vaillant argues that the "best outcome" individuals shifted to more mature defenses and adaptation modes (in our terms, more permeable walls with more articulated boundaries). In a cross-sectional study of young adult clinic outpatients, Gould found two distinct periods: 18–22 (in our model, late adolescence) and 22–28 [30]. In the former period, the individuals were in the process of taking steps *to* implement separation from parents. In the latter, the individuals felt established and secure in this separation. They were engaged in the work of being adults.

A child showing D₆ intimacy behaviors is ready to face the life event of middle adulthood (LE₇)-*appropriate marriage and family demands*. The therapist can safely facilitate this process. The young adult will forwardly regress as a function of meeting these demands to the B₇ state of normal *stagnation* characteristic of the early part of middle adulthood.

Potentially Suicidal Disintegration

The core pathology in Stage 6 is for Erikson *exclusivity*, which blocks this healthy developmental journey. It can be expressed either in what Minuchin calls enmeshment (A_6) or disengagement (C_6) [31]. Enmeshment refers to a diffuse set of self-other boundaries (in our sense, a premature removal of walls); disengagement refers to rigid self-other boundaries (a delayed removal of walls). Marcia has labelled the A_6 polarity *foreclosure* (a young adult who prematurely commits to another without sufficient exploration) and the C_6 polarity *diffusion* (an adolescent who engages in pseudo-exploration without personal commitment). The foreclosed individual is often depressed and dependent, while the diffuse individual is often withdrawn or socially isolated and out of place.

Both of these polarities are implicated in suicidal behaviors as well. Goldney found that depression (A_6) and the absence of a significant personal relationship (C_6) were associated with suicide attempts by 110 women aged 18–30 [32]. Also involved was hopelessness, as measured by the Beck Hopelessness Scale, and a history of parental conflict. Maris described the prototypic young adult female suicide as married, having children, suffering from depression, and enmeshed in a marriage that has a history of conflict. This is clearly an A_6 pattern. Lillfeld reports that job-related problems may represent a more important stressor for men than do family problems [33]. Rygnestad found an increased incidence of separation, divorce, and unemployment in both men and women suicide attempters between the ages of 13 and 88 [34]. Other studies have pointed to the role of unemployment and downward occupational mobility in adult suicide. These all represent a C_6 pattern.

A young adult exhibiting these A-C depressive-isolative behaviors is not ready for the precipitating life event (LE_7) of middle adulthood—premature *marriage and family demands*, and the therapist must attempt to delay this event or protect the individuals from it as much as possible. If he or she fails, the premature demands of social identity may well trigger an A/C suicidal crisis. Here the (A/C) $_6$ young adult would show borderline signs of both *foreclosure and diffusion* in an attempt to show *pseudo-intimacy*. This individual would be isolated within an enmeshed relationship and may even be at greater risk for suicide than before.

Stage 7 – Middle Adulthood: From Stagnation to Generativity

Stage 7 in the present model corresponds to Erikson's middle adulthood (approximately ages 34–60) with a social radius of *household and children* (SRs). It is initiated by Life Event 7 – *marital and family demands* – which forwardly regresses a syntonic *intimacy-achieving* younger adult (D_6) into the dystonic stage of *stagnation* (B_7). The middle adult often presents therapeutically as a person who has lost his or her path and has been swallowed up in the life goals of others. Here a middle adult feels overwhelmed by the demands of marriage and family (deindividuated) and finds him or herself in a state of confused withdrawal. Indeed, the very intimacy he or

she has achieved with a particular partner in Stage 6 must make room for the expanded social radius of household and children in Stage 7.

Neugarten has focused on the middle adult's increased preoccupation with his or her inner life, his or her "interiority" which enables one to look backward for the first time rather than forward. The dynamic of withdrawal to inner space is necessitated by the overwhelming demands of marriage and family life, and may be associated with a sense of "burnout," of just going through the motions. This has been associated empirically with personal feelings of worthlessness [35].

Healthy Developmental Integration

Erikson defines the core strength at this stage as *care*, which propels the stagnating middle adult forward along the developmental B->E->D axis into a syntonic state of *generativity* (D₇). Withdrawal to his or her own resources has freed the generative middle adult to get in touch with his individual sense of creativity (individuation), enabling him to enter the role of a mentor for the next generation (attachment) whether in a home or work environment in a way which integrates care for self and care for others. Shanan has labelled this midlife personality structure the "active integrated copier" investment at work is not at the expense of family relationships [36]. A number of studies have explored the difficulties women have had with this transition with regard to role strain, overload, and generally lowered morale, problems that increase with the births of subsequent children. Levinson and colleagues have conducted similar research on men [37]. They suggest that the demands of the career mentor role raise the same basic generativity issues as those associated with family parenting.

A middle-aged adult showing D₇ *generativity* behaviors is ready to face the life event of older adulthood (LE₈)-appropriate *mortality awareness*. The therapist can help to facilitate this process. The individual will forwardly regress as a function of meeting these demands to the B₈ state of normal despair, characteristic of the early part of older adulthood.

Potentially Suicidal Disintegration

The core pathology for Erikson at this stage is *rejection*, which can be expressed either in what Gutmann et al. have called *dependency* (an A₇ *constellation*) or *counter-dependency* (a C₇ structure) [38]. Stewart and Salt have reported that single "agentic" (C₇) working women became ill in response to stress [39]. In contrast, homemakers with a traditional "communal" (A₇) orientation responded to stress with depression. However, working wives integrating agentic and communal (D₇) orientations experienced no negative effects in response to stress. Similar benefits of combining agency and communion have been reported by Stewart and Malley [40] and Malley [41] with regard to both the physical and emotional health of divorcing mothers. Much of the research on this AC clinical axis emerges from the work of

Gutmann and colleagues on the “parental imperative.” Gutmann’s basic idea that the demands of parenting itself produce traditional sex-role differentiation has found considerable empirical support, even among nontraditional couples.

Gutmann goes even further to suggest associated personality structures, both men and women repressing contra-sexual tendencies in the service of parenting. Thus fathers adapt an “active mastery style” (in exaggerated form, a C_7 detached individuation structure) and mothers a “passive-nurturant style” (an A_7 deindividuated attachment structure). When the nest is emptied, the psychologically repressed returns with a vengeance [42, 43] women often shifting from passive to active styles and men in the opposite direction, i.e., the famous “midlife crossover” effect. This journey, sadly, often represents oscillation along the AC clinical axis (an exchange of symptoms if you will) rather than any true $B \rightarrow E \rightarrow D$ development. Such confusion represents one of the great dangers of this particular life stage, producing what Shanan has labelled “dependent passive copers” (an A_7 structure) or “failing overcopers” (a C_7 structure). Neither of these groups is as happy with his life as is Shanan’s D_7 “active integrated copers” group described previously.

Slater and Depue found that exit events (e.g., separation, divorce, and death) differentiate suicidal depressed individuals from non-suicidal depressed individuals more than any other kind of loss [44]. The suicidal middle-aged adult is likely to have been recently divorced or separated, to have lost a parent, or to have had a child leave home. These all represent C_7 behaviors. The A_7 polarity is manifested in depression. Depression has been shown repeatedly to be the most common psychiatric diagnosis associated with suicide among adults. Numerous studies have reported a diagnosis of affective disorder among suicidal individuals, with rates running from as low as 35% to as high as 80%. Pfeffer concludes that suicide is 30 times more prevalent among adults with affective disorder than among those not so diagnosed [45].

A middle adult exhibiting these A-C depressive-isolation behaviors is not ready for the precipitating life event (LE_8) of older adulthood – *premature goal evaluation* – and the therapist must attempt to delay this event or protect the middle adult from it as much as possible. If he or she fails, the premature demands of mortality shock may well trigger an A/C suicidal crisis. Here the (A/C) $_7$ middle adult may attempt to achieve a *pseudo-generativity* through alcoholism. Specifically, alcoholism may blur nagging feelings of unfulfillment but at the expense of increasing both *depression* (A_7) and *aggression and/or isolation* (C_7).

Male alcoholics who drink in bars may be more likely to experience alcohol-related interpersonal problems than women who are inclined to drink along at home. Further, males are more vulnerable to alcohol-related job stress and to the stress of losing their jobs. Roy and Linnoila reported the results of a group of studies that show the risk of suicide among alcoholics to be 58–85 times higher than that for non-alcoholics [46]. The suicide rate for alcoholics in the past has been estimated to be as high as 270 per 100,000 population. Several studies have shown that comorbidity of depression and alcoholism represents a greater risk for suicide than either alone. Premature exposure of the A-C middle adult to the goal evaluation demands of older adulthood (LE_8) may exacerbate a suicidal crisis.

Stage 8 – Older Adulthood: From Despair to Integrity

Stage 8 in our model refers to Erikson's older adulthood (approximately ages 60–75). The social radius (SR₈) for the older adult has become *mankind/my kind* – a differentiation of universalistic and particularistic affiliations. It is initiated by the life event (LE₈) of *unfulfilled goals* (or perhaps now meaningless fulfilled goals), a stressor that forwardly regresses the previously syntonic generative (D₇) middle adult into a profound dystonic state of *despair* (B₈). An older adult coming into treatment may report that many previous achievements have proved meaningless and many of his or her dreams are now out of grasp. The B₈ individual has lost meaning in life (deindividuation) and as such withdraws from social involvements (detachment). Life has lost its taste. The classic work by Neugarten et al. has labelled adults in this position as *unintegrated* [47]. Such people have defects in psychological functioning (deindividuation) as well as low levels of role activity and life satisfaction (detachment).

Healthy Developmental Integration

Erikson defines the core strength at this stage as *wisdom*, which guides the older adult forward along the developmental B- > E- > D axis to a position where he or she is both individuated and attached. Such a syntonic Ds individual achieves a *self-integrity* (articulated self-other boundary) based on something more profound than simple fulfilled personal goals and is thus able to reintegrate into mankind (permeable interpersonal walls) with a particularistic affirmation of his or her own kind. Neugarten et al. refer to this position as *integrated*, which is characterized by a well-functioning ego and a flexible openness with regard to environmental stimuli.

An older adult showing Ds integrity behaviors is ready to face the life event of the oldest-old (LE₉)-*appropriate mortality awareness*. The therapist can safely facilitate this process. The individual will forwardly regress as a function of meeting these demands to the B₉ state of normal incapacitation characteristic of the early part of oldest-old age.

Potentially Suicidal Disintegration

Erikson describes the core pathology at this stage as *disdain*, which can lead to fixation and oscillation on the clinical AC axis. This can be expressed either in *social isolation* (Cs personalities) or in *passive-dependence* (As individuals who have strong dependency needs and who seek responsiveness from others).

Darbonne found that suicide notes of elderly individuals included more references to loneliness and isolation than those of any other age group [48]. Miller found that older men who committed suicide were three times less likely to have a confidante than those who died of natural causes [49]. Widowhood

has been shown *to* increase the risk of suicide, especially among elderly males during the first 6 months of bereavement. Bock and Webber found that suicidal and widowed elderly people were more socially isolated than those who were non-suicidal [50].

The As polarity, in contrast, represents passive dependence often accompanying chronic illness. One study found that 85% of a group of suicide completers over age 60 were physically ill at the time they killed themselves [51]. Further evidence of the role of physical deterioration can be gleaned from studies indicating that over 70% of elderly suicides have visited a physician within the past month and that as many as 10% have consulted a physician on the actual day of the suicide. Losses are a natural part of old age, often occurring in a relatively short period of time. Depression in such a situation may become chronic and indeed is the most common of all illnesses among the aged [52]. Many researchers have estimated that a large majority of elderly suicides, perhaps as many as 80% involve significant depression (also an As structure) and cumulative loss.

An older adult exhibiting these (A/C)₈ *dependent-isolated* behaviors is not prepared for the precipitating life event (LE₉) of oldest-old *adulthood-overwhelming mortality shock*, and the therapist must attempt to delay this event or protect the older adult from it as much as possible. If he or she fails, the (A/C)₈ adult is likely to become alcoholic or dependent on drugs in an attempt *to* elevate his or her spirits and ease his or her aches, pains, and fears of death. Such an attempt at *pseudo-integrity* is unfortunately extremely disintegrative. The interactive effects of alcohol abuse with over-the-counter and prescription drugs may result in a clouding of consciousness and increase the likelihood of depression and suicidal behavior; Miller found that approximately 25% of a group of elderly male suicides were alcoholic or had significant drinking problems and that 35% of this group were addicted to or heavily dependent on drugs [53].

Stage 9 – The Oldest-Old: From Incapacitation to Generational Continuity

Stage 9 in our model, the oldest-old, has not been covered specifically by Erikson nor has it been studied as extensively as some of the earlier adult stages. Peck represents a classic attempt to extend Erikson's thinking to the oldest-old, offering finer distinctions in the second half of life than he felt were made by Erikson [54]. Issues of old age, as distinct from those of middle age that have been offered by Peck, are ego-differentiation versus work-role preoccupation, body transcendence versus body preoccupation, and ego transcendence versus ego preoccupation. As we have mentioned before, Newman and Newman have tried more recently to extend Erikson's thinking to the oldest-old, suggesting the life issue here is "immortality versus extinction." Many studies in geriatric psychology and psychiatry have emphasized depression among aged individuals; Berger and Zarit [55] have studied later life paranoid states, and Cath [56] has differentiated depression and depletion among individuals at this age.

Healthy Developmental Integration

Our model sees the oldest-old stage as initiated by the staggering life event or stressor of *physical decline and awareness of mortality and life-finiteness* (LE₉). Gutmann et al. [38] have labelled it “life cycle shock” or “existential stress” that upsets the syntonetic equilibrium (D₈) achieved by the *integrity-achieving* older adult and forwardly regresses the now oldest-old into the helpless dystonic position of *incapacitation* (B₉). A previously healthy older adult may now need a cane or a walker – or even a wheelchair. Memory may fail, as may kidneys. Previously reliable social supports may themselves have died and the individual may become aware of his own limited time. In short, the now oldest-old individual may find himself both enfeebled (deindividuated) and isolated (detached).

What is critical here is how the individual manages to transcend the present-centered integrity of mankind/my kind to deal with his or her once again expanded social radius (SR₉) of *present versus future generations*. Does the incapacitated or terminal oldest-old behave like dying King Berenger The First in Ionesco’s [56] brilliant satire “Exit the King” losing all interest in the present and future world? “I am only present in the past,” says the king (p. 50) in response to his second wife Marie’s attempts to console him. When she later (p. 67) points to the expanding future, “the younger generation’s expanding the universe, ... conquering new constellations, ... boldly battering at the gates of Heaven,” Berenger again cuts himself off, “I’m dying, .. I’m dying, ... they can knock them flat for all I care.” Or does the incapacitated oldest-old adult utilize his core strength at this stage, *faith*, to carve out a historical self (individuation) that allows the individual to connect in a genuine way (attachment) with future generations (D₉)?

Lifton [57] has called this a “sense of immortality,” which overcomes a preoccupation with one’s own ego, body, and generation through a faith, a vested interest if you will, in future generations. Indeed, Augustine and Kalish propose that older people and dying people of all ages need to establish some kind of attachment that will be ongoing after the death of the body, whether it be through a divine being, being remembered by others, through accomplishments, through progeny, or through association with a cause or ideology [58]. This sense of a *transgenerational continuity* is deepened by the oldest-old taking on the role of transmitter of history to the next generation and helps to prepare the individual for his own death – the final life event (LE₁₀).

An oldest-old adult showing transgenerational continuity behaviors is ready to face the final life event (LE₁₀)-appropriate personal death. The therapist can safely facilitate this process calling on the individual’s sense of him or self as a link between the generations.

Potentially Suicidal Disintegration

The core pathology at his or her stage is what Newman and Newman have labelled *doubt*, a profound uncertainty that there is anything beyond the present ego, body,

and life-finiteness. It tends to truncate the individual's sense of time in the present and may be expressed in one of two forms.

One expression is what Cumming and Henry have labelled *disengagement* (a C_9 structure), which is indicated by increased preoccupation with the self and decreasing emotional investments in persons and objects in the environment [59]. When such social withdrawal is voluntary and mutual, it may represent a normal reconsolidation of older adulthood. However, when it is not so mutual or voluntary, it may represent a more pathological structure. This structure may also have a *paranoiac* aspect to it that may involve suspicions and accusations of others.

The second expression is paraphrased from the work of Havighurst et al. and may be labelled *overactivity* (an A_9 structure) where the individual trivializes him or herself through mindless activities designed to numb him or her to his or her terminal position in the life cycle [60].

While Lawton [61] has reported that residents of institutions for the aged seek out areas of high activity, Lemon et al. [62] find that activity per se was not found to be significantly related to life satisfaction among new residents of a retirement community. In extreme form, an obsession with overactivity may block the private time necessary to achieve the syntonic state of transgenerational continuity and reflect aspects of the *depressed* state discussed by Levin [53] and by Cath [63] with an attendant loss of self-esteem. One recent study points to the greater preponderance of these pathological A and C structures among clinical (depression, personality disorders, paranoia, and anxiety disorders) as opposed to normal older adults. Two other studies suggest that a major developmental component of normal older adults (including the oldest-old) is the dissipation for both men and women of the rigid gender differentiation evoked at earlier life stages. Here, finally, similar life experiences enable the oldest-old to integrate individuation and attachment (the developmental B->E->D axis) in a way not totally determined by rigid gender stereotypes.

An oldest-old adult exhibiting these A-C *overactivity-disengagement* behavior is not ready to face death openly and may disintegrate (A/C)₉ if the realization is imposed on him or her. In this case, the therapist must attempt to protect the individual from death awareness as much as possible. If he fails, the individual may fall apart, attempting to simulate a sense of transgenerational continuity through a fusing of the irreconcilable polarities of disengagement and overactivity (A/C)₉.

Up to this point, this chapter has attempted to provide the working clinician with a developmental guide to recognize suicide risk across the life span. For an individual developing normally on the B->E->D axis, a new life event at the appropriate time offers the potential for integrated development and forward regression from one stage to the next. Here, the therapist should encourage or facilitate the new life event. For an individual on the A<->C clinical axis, a new life event may be overwhelming, pushing the individual into an A/C attempt to simulate D-level integration. The pseudo-D position is highly disintegrative, and here, the life event may become a triggering event for suicide. The chapter offers the clinician a guide for differentiating B->E->D versus A<->C behaviors across successive life stages.

An Application to Ancient Narratives: Preventing Suicide and Valorizing Life in Biblical Versus Graeco-Roman Narratives

Now we focus on how well our two-axis model can explain the differences in reaction to life stressors experienced by matched biblical versus Graeco-Roman narratives. This builds on a call over 60 years ago by Erich Wellisch [64], medical director of Grayford Child Guidance Clinic in England for a “biblical psychology, arguing that:

The very word “psyche” is Greek. The central psychoanalytic concept of the formation of character and neurosis is shaped after the Greek Oedipus myth. It is undoubtedly true that the Greek thinkers possessed an understanding of the human mind which, in some respects, is unsurpassed to the present day, and that the trilogy of Sophocles still presents us with the most challenging problems. But stirring as these problems are, they were not solved in the tragedy of Oedipus. In ancient Greek philosophy, only a heroic fight for the solution but no real solution is possible. Ancient Greek philosophy has not the vision of salvation. . . There is need for a Biblical psychology (p. 115).

Faber [65] identifies some 16 suicides and self-mutilations among the 223 characters depicted in the 26 surviving tragedies of Sophocles and Euripides yielding a suicide rate of 7.2% (see Table 1). Applying Durkheim’s typology, most of Sophocles’ depicted suicides are egoistic, while most of the suicides depicted by Euripides’ are altruistic. Several of each are anomic. Table 3 applies Durkheim’s typology to suicides in Greek tragedy.

Table 4 applies Durkheim’s terminology to the much smaller number of biblical suicides: only six suicides can be found in the Hebrew Scriptures. Three can be classified as egoistic (Ahitophel, Zimri, and Abimelech) and three are altruistic (Saul, Saul’s armor bearer, and Samson). The important point here is the far fewer number of suicides in Hebrew Scriptures.

Some 2855 different people (2730 men and 1125 women) are mentioned in the 39 books of the Hebrew Scriptures spanning a period of 3,330 years, [66]. Only six are identified as completed suicides (see Table 3), yielding an overall suicide rate of 6/2855 or 0.02%, including none by women. A huge chi-square statistic emerges when we compare this biblical rate of 0.02 to the 9.02% suicide rates in the 26 plays of Sophocles and Euripides (chi-square = 141.39 $p < 0.001$).

In addition, the Hebrew Scriptures present six suicide-prevention narratives absent in Greek writing (see Table 5).

This chapter concludes the basic thinking of our bidimensional approach to Erikson by comparing biblical and Graeco-Roman narratives confronted with regard to seven evidence-based respective suicide risk factors or stressors [67]: (1) Feeling isolated and ignored; (2) Feeling one’s life is without meaning; (3) Feeling exiled from one’s home or homeland (feeling as a refugee or an outcast); (4) Feeling unable to be oneself with others; (5) Feeling one is alone in one’s life mission; (6) Feeling abandoned by one’s child leaving the family nest and building his/her own life; and (7) Feeling doomed by a dysfunctional (and even incestuous) family of origin. While the Greek characters remain fixated on the AC clinical axis and self-destruct in one

Table 3 Suicides in Greek tragedies of Sophocles and Euripides

Character	Gender	Source	Method	Type
Ajax	M	Ajax (Sophocles 1938)	Sword	Egoistic
Oedipus	M	Oedipus Rex (Sophocles 1938)	Self-blinding	Egoistic
Jocasta	F	Oedipus Rex (Sophocles 1938)	Self-hanging	Egoistic
Haemon	M	Antigone (Sophocles 1938)	Sword	Egoistic
Eurydice	F	Antigone (Sophocles 1938)	Knife	Egoistic
Deianera	F	The Trachinae (Sophocles 1938)	Sword	Egoistic
Heracles	M	The Trachinae (Sophocles 1938)	Self-burning	Anomic
Antigone	F	Antigone (Sophocles 1938)	Self-hanging	Anomic
Hermione	F	Andromache (Euripides 1938)	Suicidal threats	Anomic
Phaedra	F	Hippolytus (Euripides 1938)	Self-hanging	Anomic
Evadne	F	The Suppliants (Euripides 1938)	Self-burning	Altruistic
Iphigenia	F	Iphigenia in Aulis (Euripides 1938)	Allows herself to be killed by axe	Altruistic
Menoeceus	M	The Phoenissae (Euripides 1938)	Jumps into fire	Altruistic
Macaria	F	The Heracleidae (Euripides 1938)	Allows herself to have throat cut	Altruistic
Polixena	F	Hecuba (Euripides 1938)	Allows herself to be killed by sword	Altruistic
Alcestis	F	Alcestis (Euripides 1938)	Poisons herself	Altruistic

M = Male, F=Female

Table 4 Suicides in the Hebrew Bible

Character	Gender	Source	Method	Type
Saul	M	1 Sam. 31:4 1 Sam 1:6 1 Chron. 10:4	Self-stabbing (falls on sword)	Covenantal
Saul's Armor Bearer	M	1 Sam. 31:5 1 Chron. 10:5	Self-stabbing (falls on sword)	Altruistic
Ahitophel	M	2 Sam 17:23	Self-strangling	Egoistic
Zimri	M	1 Kings 16:18	Self-burning	Egoistic
Abimelech	M	Judg. 9:54	Self-stabbing	Egoistic
Samson	M	Judg 6:30	Self-crushing	Covenantal

M = Male, F=Female

Table 5 Suicide preventions in the Hebrew Bible

Character	Gender	Source	Method
Rebecca	F	Genesis 27–28	Appropriate matchmaking
Moses	M	Numbers 11	Support and practical advice
Elijah	M	1 Kings 18–19	Protected withdrawal and nurturance
Jonah	M	Jonah	Protected withdrawal and guidance
David	M	Psalms 22	Renewal of faith in God
Job	M	Job	Renewal of relationship

M = Male, F = Female

form or another, the biblical figures recover and move ahead on the B->E->D developmental axis.

The life-promoting biblical stories of Elijah, Job, David, Moses, Jonah Rebecca and Ruth are contrasted to the matching suicidal Graeco-Roman stories of Ajax, Zeno, Coriolanus, Oedipus, Narcissus, Phaedra, and Antigone.

Feeling Isolated and Ignored: Treating the Ajax Syndrome with the Elijah Intervention

First, we compare the Greek suicide story of Ajax [68] with the biblical suicide-prevention story of Elijah [69] with regard to the suicidal implications of being isolated.

The Ajax Syndrome

After the death of Achilles in the Trojan War, the Greek leaders choose Odysseus over Ajax to inherit his arms, leaving the latter feel his honor is stained. Ajax sets out at night to murder Agamemnon, the leader of the Greek forces, and his brother Menelaus. The goddess Athena becomes angry and makes Ajax mad. Ajax slaughters sheep in the army's flocks, and leads others to his tent, thinking that he is killing/torturing the Greek leaders themselves. As his madness passes, Ajax retreats humiliated and despondent into his tent, not disguising his suicidal thoughts.

Ajax cries, something he had always refused to do as it "befitted cowards only" (Sophocles, *Ajax*, l. 320). "Ah me, the mockery," he cries and continues "To what shame am I brought low" (l. 365). Ajax is overwhelmed by what has happened to him and sees no way out other than suicide. He has not received positive support from others, including his brother. Teucer only belatedly sends a message to the Greek chieftains ordering that Ajax not leave his tent alone – Ajax has already done so and has fallen on his sword (Sophocles, *Ajax*, ll.748-755, 848-849, 865).

The Elijah Intervention

The Biblical prophet Elijah represents a contrasting example of how to treat a depressed and suicidal person. As the result of an ongoing conflict with Jezebel who wants to kill him (*1 Kings* 19: 1-2), Elijah is at the end of his rope and says he

Table 6 Elijah against Ajax

Stage	Ajax	Elijah
1. Precipitating stressor	Ajax is humiliated by both Agamemnon and Athena (Position A)	Elijah is overwhelmed and exhausted from his harassment by Queen Jezebel (Position A)
2. Reaction	Ajax says he wants to die (Position A)	Elijah says he wants to die (Position C)
3. Response of others	Ajax is allowed to leave his tent alone (Position C)	Elijah is sent an angel who brings him food, drink, and companionship, and lets him rest. (Regression to Position B)
4. Effect	Ajax kills himself by falling on his sword (Position A/C)	Elijah recovers his strength and continues his mission in Horeb and is given the younger Elisha to help him. (Advance to Position D)

cannot go on and expresses a wish to die (*I Kings* 19: 3-4). God listens to him and takes his statement to heart. He sends an angel to Elijah providing him with food and drink and allowing him to rest (*I Kings* 19: 5-8). Elijah recovers his strength and goes on to Mt. Horeb with the help of young Elisha (*I Kings* 19: 15-18).

A contrast of these two narratives is presented in Table 6.

Feeling One's Life Is Without Meaning: Treating the Zeno Syndrome with the Job Intervention

Here we compare the Greek suicide story of Zeno [70] and the biblical suicide-prevention story of Job [71] with regard to response to a misfortune and the importance of having an intrinsic life purpose rather than destructively searching for meaning.

The Zeno Syndrome

The inability to create meaning in one's life often leads to feelings of utter despair. It can drive a person to very extreme, often destructive attitudes to try to artificially manufacture meaning. Zeno, founder of the Stoic school of philosophy, wrenched his toe on the way home from lecturing at the *Stoa* (porch). He catastrophizes this objectively minor mishap as a "sign from the gods that he should depart" and voluntarily holds his breath until he dies (Diogenes Laertius, *Lives of Eminent Philosophers*, 7.28). Zeno's overinterpretation may represent his attempt to find meaning and purpose in an otherwise hopeless and meaningless world.

The medically impossible depiction of Zeno holding his breath until death negates the involuntary aspect of breathing and the Biblical conception that God breathes life into man and takes it away (Gen. 2:7). Zeno, like other Greek and Roman stoics, needs to control the conditions around his death, equating this control with a tragically tinged sense of freedom [72].

The Job Intervention

Job, in contrast, does not commit suicide despite being assailed by far more serious misfortunes – the loss of his wealth, his family, and his health. His wife tells him to curse God and die (Job 2: 9) and his friends tell him to admit he deserves his punishment, but he refuses because he knows it is not true (Job 4-32). Job certainly complains bitterly deeply grieved and indeed wrestles with suicide, indeed stressing the same method of death, *strangling*, as did Zeno. “So that my soul chooseth strangling, and death, rather than these bones.” (Job 7: 15). However, Job does not act on this feeling, reaffirming his relationship with his Creator: “Though He slay me, yet will I trust in Him” (Job 13: 15). Exline et al. [73] point to the importance of arguing within a relationship without leaving it. Job is anchored in a sense of a personal Creator who is with him from the moment of his birth and will be with him into his death and beyond. Thus, he can withstand far greater misfortune than can Zeno without the need to attribute cosmic meaning to it.

In contradistinction to Zeno who is improbably described as “holding his breath until he dies,” the book of Job stresses that it is God himself that has given Job the breath of life. “The spirit of God hath made me, and the breath of the Almighty giveth me life.” (Job 33: 4). If He withdraws that breath, man returns to the dust from which he sprung (cf. Psalms 104:29). And when God restores the breath, man rises again and renews the face of the earth. “Thou sendest forth Thy spirit, they are created; and Thou renews the face of the earth.” (Psalms 104:30).

Life for Job has inherent meaning and purpose, and this represents the best alternative and antidote to the obsession with dignity and rational suicide so endemic to Zeno the Stoic and contemporary culture.

A contrast of these two narratives is presented in Table 7.

Table 7 Job against Zeno

Stage	Zeno	Job
1. Precipitating stressor	Zeno the Stoic trips and stubs/ breaks a toe on the way back from giving a lecture at the Stoa (Position A)	Job suddenly and unexpectedly loses his property, his children, and his health (Position B)
2. Reaction	Zeno interprets this as a sign from the gods he should depart (Position C)	Though Job complains, he maintains his innocence faith in God despite his misfortunes (Position E)
3. Response of others	No mention made of reaction of others	Job’s friends tell him that he must be guilty, and his wife tells him to curse God and die (Position E)
4. Effect	Zeno immediately holds his breath until he dies (Position A/C)	Job steadfastly maintains his faith in God while proclaiming his innocence and he is restored (Position D)

Feeling Exiled from One's Home or Homeland (as a Refugee or Outcast): Treating the Coriolanus Syndrome with the David Intervention

Let us compare the Roman story of Coriolanus [74–76] and the biblical story of David [77] with regard to constructively dealing with the experience of exile and/or being a refugee from one's homeland.

The Coriolanus Syndrome

Roman historians Plutarch [74] and Livy (Titus Livius) [75], and Shakespeare [76] all tell of the legendary Roman commander Gnaeus Marcius whose military valor at Corioli against the Volsci, the enemies of Rome in the fifth century B.C.E., won him the honorary name of Coriolanus. Plutarch describes Marcius as a man of great energy and strength of purpose but combined with so violent a temper and self-assertion that he could not cooperate with people. After his heroism and brilliance in defeating the Volsci, Marcius becomes embroiled in angry arguments between the upper and lower classes of Rome, and his outspoken insults to the plebeian's leads to his banishment and almost his execution, despite his glorious military services.

Obsessed with wreaking revenge on Rome, Marcius (Coriolanus) goes over to the Volsci, enemies of Rome, and persuades them to attack Rome. As Marcius' Volsci army sits camped before Rome, two delegations came from the city but could not persuade him to desist. Roman women then came forth spontaneously to the camp, accompanied by Marcius's mother (Volumnia), his wife, and children. Marcius relents and withdraws the Volsci army. Plutarch says that he was murdered by the Volsci shortly after this withdrawal. Livy in his history of Rome tells of another report that Marcius lived on for many years and endured the miseries of exile. Though not a suicide story *per se*, there is no question that the rigidity of Coriolanus helped provoke his death.

The David Intervention

David was also a war hero, but of a vastly different sort, described as playing the lyre for King Saul, and is loved by the people. He slays the Philistine giant Goliath not by brute strength but through agility and the use of a simple slingshot. Later, his life threatened because of the jealousy of King Saul, David flees his native Israel with a band of men to live under the Philistines, longtime foes of Israel (1 Samuel, 27). Yet here the similarity to Marcius ends. David leaves not because he hates his countrymen but to save his life from King Saul's anger against him. David is no rigid perfectionist but remains deeply human. Even in exile, David does not turn from his love of Israel, despite Saul's anger at him. In the period that David and his troop live among the Philistines, he leads his troops in war against common enemies of Israel and the Philistines, he is spared the conflict of having to fight for the Philistines in a decisive battle against Israel (1 Samuel 29: 6-11). David becomes King of Israel after Saul's death in this battle. As king, David (2 Samuel 6: 12-23) does not show contempt towards the common people as Coriolanus did to the plebeians in Rome.

Table 8 David against Coriolanus

Stage	Coriolanus	David
1. Precipitating stressor	Coriolanus, a Roman military hero, antagonizes his countrymen and is exiled from Rome (Position C)	David, a military hero in Israel, flees from Israel to escape Saul’s murderous jealousy and wrath (Position B)
2. Reaction	Coriolanus joins the Volsci, the enemy of Rome, in order to wreak vengeance against Rome	David joins the Philistines, the enemy of Israel, but maintains his love of Israel (Position E)
3. Response of others	The Romans fear Coriolanus will lead the Volsci in battle against Rome, yet he is still not trusted by the Volsci and ultimately does not attack Rome (Position A)	David avoids fighting against his beloved Israelites, attacking instead common enemies of Israel and the Philistines. (Position E)
4. Effect	Coriolanus withdraws the Volsci from attacking Rome but remains condescending and insulting to the Volsci who murder him. (Position A/C)	David is spared fighting against the Israelites and is thus able to be loyal both to King Achish of the Philistines and to Israel. David subsequently becomes King of Israel (Position D)

Rather, David dances with the people when the ark is brought into Jerusalem, even though this earns him the contempt of his wife Michal.

A contrast of these two narratives is presented in Table 8.

Feeling One Is Unable to Be Oneself with Others: Treating the Narcissus Syndrome with the Jonah Intervention

Let us compare the Greek suicide story of Narcissus [78, 79] with the biblical suicide-prevention story of Jonah [80] with regard to the importance of being able to integrate self and other.

The Narcissus Syndrome

Greek thought sees self and other as fundamentally opposed. One wins at the expense of another losing. The Apollonian side of Greek culture represents a walled-off and disengaged intellect. The Dionysiac side portrays an enmeshment which destroys individual boundaries. The terms “narcissism” and “narcissistic” have become almost bromides in modern society to describe people who are extremely selfish and self-involved. The actual story of Narcissus provides a much richer picture ending in his suicide. Strangely, the suicidal end of the story is largely ignored in modern psychology and psychiatry. Narcissus cannot successfully integrate self and other.

The earliest sources of the myth of Narcissus have long since been lost. Our most complete account from antiquity is in Ovid’s *Metamorphoses* dated from 43 BCE to

17 CE. Narcissus is born out of a rape of his mother Lirope by a river god. When Lirope enquires from the Greek seer Tiresias about whether her son will live to a ripe old age, she receives a strange answer: He [Narcissus] will live a long life as long as he does not come to know himself (ibid, 3: 343-350).

Narcissus grows to be a vain young man, so physically beautiful that many fall in love with him by simply looking at him. (ibid, 3: 359-378). Narcissus seems to be self-absorbed, treating his lovers of both sexes as mere mirrors of himself. Echo, the nymph who loves Narcissus in vain, is transformed, left merely repeating the words he says – as an echo (ibid, 3: 379-352). One would-be lover who feels scorned prays to the god of fate, Nemesis, and asks that Narcissus too fall hopelessly in love and be unable to achieve his desire (ibid, 3: 405-6). Soon, Narcissus sees a beautiful youth in a pond, not realizing it is his own reflection. Narcissus is obsessed with the image in the brook and looks at it night and day (ibid, 3: 414-454).

Ultimately, however, Narcissus recognizes the face in the brook is his (ibid, 3: 463-473). The reflection becomes simultaneously an ideal and a mirror. He is not self-invested, but self-empty, driven to grasp his self, which has now been projected onto the outside world. Such a psychotic juxtaposition rips Narcissus apart. As Ovid expressed it, “How I wish I could separate myself from my body.” Narcissus finally becomes aware of the unobtainability of the figure he sees in the pond – it is his own reflection. He pines away until he dies, mourning the youth he loves in vain.

The suicidogenic element in the myth of Narcissus is the inability of Narcissus to successfully integrate his individuation and attachment behaviors. First he is individuated at the expense of attachment (egoistic); then he is attached at the expense of individuation (i.e., altruistic). Finally, he is overwhelmed by the irreconcilable confusion between his individuation and attachment issues (i.e., anomic) and resolves the conflict through self-murder, portrayed in Ovid (ibid, 3, 497-50) as pining away, and in Conon as actively stabbing himself in his chest (Conon, 1798, *Narrationes*, 24).

The Jonah Intervention

The story of Jonah begins with Jonah placed in an essentially similar individuation-attachment dilemma. God calls on Jonah to go to warn the people of Nineveh of their wickedness. Jonah does not want to go, but he is too God-fearing to defy the command and too strong-willed to submit. In desperation, he flees to Tarshish and tells his shipmates to throw him overboard when a terrible storm threatens the ship (Jonah 1: 1-12). The story could thus end in Jonah's suicide, but it does not – God intervenes as a protective parent, swallowing Jonah in the protective stomach of a great fish until he overcomes his confusion. Jonah prays to God from the belly of the fish until he becomes stronger. Then the fish vomits him out on dry land (Jonah 2).

This pattern repeats itself. God again commands Jonah to go to Nineveh. This time Jonah goes and gives the people God's message. They repent and are saved (Jonah 3: 1-10). Jonah becomes angry and again expresses the wish to die and sits on the outskirts of the city (Jonah 4: 1-3). Again, God intervenes, sheltering Jonah with

a leafy bush from the burning sun (Jonah 4: 6). After a worm destroys the protective bush, Jonah again expresses suicidal thoughts (Jonah 4: 7-8). God intervenes, this time engaging Jonah in a dialogue to teach him the message of *teshuvah* (repentance) and divine mercy and that he can reach out to another without losing himself (Jonah 4: 9-11). Biblical thinking sees self and other in harmony. Jonah avoids the polarities of disengagement and enmeshment. In the words of the biblical sage, Hillel, “If I am not for myself, who will be for me? If I am only for myself, what am I? If not now, when?” (*Pirke Aboth* 1: 14).

A contrast of these two narratives is presented in Table 9.

Table 9 Jonah against Narcissus

Stage	Narcissus	Jonah
1. Precipitating stressor	Narcissus born of a rape of his mother. Prophesied to have a long life if “He does not come to know himself.” (Position A)	God asks Jonah to go and warn the wicked people of Nineveh to repent lest they avoid great punishment. Jonah does not want to go and runs away to Tarshish to avoid the conflict. (Position A/C)
2. Reaction	The beautiful Narcissus heartlessly exhibits <i>hubris</i> by rejecting would-be lovers of both genders. (Position C)	God sends a great storm when Jonah is on a ship. When his identity as a Hebrew is discovered, he tells his shipmates that he is the reason for the storm and asks his shipmates to throw him overboard. However, rather than let Jonah drown, God sends a big fish to swallow him, thus allowing him to recover his strength. (Position B)
3. Response of others	Narcissus is brought down by <i>Nemesis</i> and becomes completely infatuated with a face he encounters in a brook. (Position A/C)	After the fish vomits out the restored Jonah unto dry land, God again asks him to go to Nineveh to warn its inhabitants to repent and change their ways. (Position E)
4. Effect	Narcissus realizes the face in the brook is his and thus unobtainable. He commits suicide, either in a passive (pining away) or active (stabbing himself) manner, depending on the source. (Position A/C)	Jonah warns the people of Nineveh but becomes suicidal again and sits outside the city walls under a hot sun. God again protects Jonah through shielding him from the sun with a large gourd. Ultimately God removes the gourd, and in addressing Jonah’s complaint, teaches him the lesson of mercy and compassion – that he need not lose himself in reaching out to others. (Position D)

Feeling One Is Alone and Unsupported in One's Life Mission: Treating the Oedipus Syndrome (171) with the Moses Intervention (172)

Let us compare the Greek suicide/self-mutilation story of Oedipus [81] with the biblical suicide-prevention story of Moses [82] regarding addressing the suicidal implications of feeling one is alone in one's life mission.

The Oedipus Syndrome

Laius, King of Thebes, hears from an oracle that his newborn son Oedipus will murder him and marry his wife when/if he grows up. He unsuccessfully attempts to have him killed but Oedipus is saved and raised by the King and Queen of Corinth. As a young man, he hears his identity questioned at a dinner party. He goes to the Oracle of Delphi to inquire about his identity. The Oracle does not answer him but instead prophesies that he is destined to kill his father and marry his mother, whom he mistakenly thinks are the King and Queen of Corinth. Trying to avoid doing this, Oedipus flees to Thebes and kills an older man after an altercation on the road (not realizing the man is Laius) and is given his widowed mother (also unknown) as a wife as a reward after he solves the riddle of the Sphinx who has been terrorizing Thebes. He begets four children with her. Oedipus does not seem able to solicit or accept help from anyone, being done in by riddles from the Oracle of Delphi, convoluted responses from the prophet Teiresias, and mistrust of his brother-in-law Creon. Nowhere does Oedipus receive any real help he can fully trust (Sophocles, *Oedipus Rex*; Aeschylus, *the Seven against Thebes*).

The Moses Intervention

For Moses also, birth brought danger of death. His life is threatened by Pharaoh's decree to throw all males born among the Israelites into the Nile. Moses is sent away by his natural family when he is 3 months old to save his life and is rescued by Pharaoh's daughter who sees him floating in the river in an ark with bulrushes and brings him into the house of Pharaoh himself to raise him. Significantly Moses' sister Miriam watched from a distance to remain aware of what would happen to him.

Moses does not consciously attempt to seek clues about his destiny but the account of Moses going among his Hebrew "brethren" one can see his latent identification: he kills an Egyptian attacking a Hebrew (Exodus 2: 11-12). Moses subsequently chances upon the burning bush and encounters the Hebrew God, who informs him of his mission to save the Children of Israel from Pharaoh. Yet Moses has a speech impediment – he stutters – and is genuinely helped in his mission by his older brother Aaron who does the public speaking for him (Exodus 7). Despite Moses's misgivings as to his own abilities, he does ultimately agree to God's call and leads the Children of Israel out of slavery.

Yet he subsequently does feel overwhelmed by his task and unable to go on, crying to God in his despair: (Numbers 11: 12). The demands are too great, and Moses feels inadequate to the task. He doubts all the people can be provided for (Numbers 11: 13, 21-23) and blames himself (Numbers 11: 14), challenging God to

Table 10 Moses against Oedipus

Stage	Oedipus	Moses
1. Precipitating stressor	Oedipus’s mother sends the infant Oedipus away to be exposed on mountain top and die. (Position C)	Moses’s mother sends the infant Moses away to save him from being killed by Pharaoh. (Position B)
2. Reaction	Oedipus is rescued and raised by the king of a neighboring state, Corinth (Position A)	Moses is rescued and raised by the daughter of Pharaoh (Position E ₁)
3. Response of others	Oedipus’s identity is questioned, and he has no one to talk to. He attempts unsuccessfully to gain usable information from the Oracle of Delphi, who speaks in riddles and entraps Oedipus into patricide and incest. (Position A/C)	Moses sees an Egyptian mistreating an Israelite and kills him with a rock. He flees Egypt, but God appears to Moses and chooses him to lead the Israelites against Egypt and give him necessary help (Aaron, a Sanhedrin). (Position E ₂)
4. Effect	Oedipus attempts to save Thebes from a plague but is undone by misinformation and riddles from others, resulting in Oedipus’s self-blinding as well as many killings and suicides. (Position A/C)	Moses is able to carry out his mission in leading the Israelites to freedom. (Position D)

kill him (Numbers 11: 15). God responds and provides Moses with the help of 70 people, a Sanhedrin (Numbers 11: 16-7).
A contrast of these two narratives is presented in Table 10.

Feeling Abandoned by One’s Child Leaving the Family Nest and Building His/Her Own Life: Treating the Phaedra Syndrome with the Rebecca Intervention

Here we compare the Greek suicide story of Phaedra [83] with the biblical suicide-prevention story of Rebecca [84] regarding addressing the suicidal implications of feeling one’s child is going on to live his/her own life.

The Phaedra Syndrome

In Euripides’ *Hippolytus*, Phaedra, the wife of King Theseus, is caught in a miserable family situation, and at the same time, she has unrealistic expectations of herself. By the goddess Aphrodite’s design, she falls madly in love with her stepson, Hippolytus. Though she resists her passion, her servant betrays her secret to Hippolytus. Phaedra then hangs herself (Il. 776-779), leaving behind a note that falsely accuses Hippolytus of raping her (Il. 882-898). Theseus believes the note and pronounces a curse of death on his son. The curse is soon fulfilled, and the truth of Hippolytus’s innocence is revealed too late. According to this play, the gods are selfish and cruel, utterly

without compassion toward humans. Aphrodite plots to destroy Hippolytus for living in chastity and for his hatred of women (ll.665-67) by filling his stepmother, Phaedra, with passion for him, and turns the heart of his father against him.

Phaedra mixes an exaggerated sense of honor and guilt with a tendency toward self-punishment: (l. 317). She must hide her passion to save her honor: (l. 327) – even if it means suicide (l.331). There is no stopper in Phaedra’s rush toward suicide. She is too overwrought to remain silent, Aphrodite works against her, and her nurse betrays her by spilling the secret of her passion. Death seems to be the only cure: (l. 397). As she expresses it with finality, “I know only one way, one cure for these my woes, and that is instant death” (l. 599).

The Rebecca Intervention

The story of the biblical matriarch Rebecca is very different. After participating in the deception by which they have obtained Isaac’s blessing, Rebecca tells Jacob to go away to her brother Laban, so that he won’t be killed by his brother Esau who feels that Jacob has stolen his father’s blessing that rightly belongs to him (Gen. 27: 42-45). Immediately afterward, Rebecca tells Isaac that her life has been made miserable by Esau’s Hittite wives, and she worries that Jacob may similarly marry a daughter of Heth, the Canaanite:

And Rebecca said to Isaac, “I am weary of my life because of the daughters of Heth. If Jacob takes a wife of the daughters of Heth, like these who are the daughters of the land, what good shall my life be to me?” (Gen. 27:46).

Although this has been read as a “suicidal ideation” narrative, such an interpretation may be somewhat overdrawn. Rebecca’s words seem more like a message to her husband: “Please fix this situation because I can’t stand it!”. In any case, the tactic works, and Isaac commands Jacob to not marry one of the daughters of Canaan, who are so offensive to Rebecca and instead tells him to go to Laban and marry one of his daughters. Rebecca is relieved, and there is no more mention of her “suicidal” musings (Gen. 28:1-4). Rebecca is not being seductive towards her son, nor is she trying to block him from living his own life. What she wants is that Jacob marry a suitable partner. When Isaac listens to her, Rebecca’s suicidal impulse is resolved.

A contrast of these two narratives is presented in Table 11.

Feeling Doomed by a Dysfunctional Family of Origin: Treating the Antigone Syndrome with the Ruth Intervention

Let us compare the Greek suicide story of Antigone [85] with the biblical life-affirming story of Ruth [86] with regard to addressing the suicidal implications of coming from a dysfunctional (e.g., incestuous) family of origin.

The Antigone Syndrome

Greek thought posits that one is doomed when being born of a dysfunctional family. Oedipus expresses this succinctly “For now. I am forsaken of the gods, son of a

Table 11 Rebecca against Phaedra

Stage	Phaedra	Rebecca
1. Precipitating stressor	Phaedra falls passionately in love with her stepson Hippolytus, wanting him for herself (Position C)	Rebecca is concerned that her son Jacob will marry a totally unsuitable Hittite woman (Position B)
2. Reaction	Phaedra attempts to resist her passion but becomes very depressed (Position A)	Rebecca tells her husband Isaac that “her life will not be worth living” if Jacob marries a Hittite woman, like his brother Esau did. (Position E ₁)
3. Response of others	Phaedra’s servant betrays the secret of her infatuation to Hippolytus (Position A/C)	Isaac sends Jacob away to marry a daughter of Rebecca’s brother Laban (Position E ₂)
4. Effect	Phaedra hangs herself and leaves a note to her husband Theseus falsely accusing Hippolytus of raping her, leading to his death (Position A/C)	Rebecca is satisfied and does not speak of suicide again (Position D)

defiled mother, and successor to his bed who gave me my own wretched being.” (Sophocles, *Oedipus the King*, ll. 1359-1361). This is played out in the story of Antigone, daughter (and half-sister) of Oedipus. She is the product of the incestuous union of Oedipus and his mother Jocasta.

Antigone is unable to separate herself from the incestuous nature of her birth. “From what manner of parents did I take my miserable being? And to them I go thus, accursed, unwed, to share their home” (Sophocles, *Antigone*, l. 869). Antigone (which in ancient Greek literally translates to “opposed to motherhood or anti-generative”) ultimately hangs herself after being buried alive for trying to bury her dead brother Polyneices, a rebel against Thebes, against the order of her uncle Creon, the ruler of Thebes. Strikingly, Antigone says she values her brother more than a husband or a child because the latter can be replaced while the former cannot (Sophocles, *Antigone*, 907-913).

The Ruth Intervention

Biblical thought offers a hopeful alternative. One can overcome the effects of a dysfunctional or even an abandoning family. “Cast me not off, neither forsake me, O god of my salvation. For though my father and mother have forsaken me, the Lord will take me up.” (Psalm 27: 9-10). When the sinful people of Sodom are destroyed, Lot and his two daughters escape thinking their father is the last living man, they get him drunk and have sexual relations with him, so that humanity will not perish (Genesis 19: 31). Out of the union of Lot and his older daughter come the people from Moab (literally, “from the father” in Biblical Hebrew). Thus, Ruth also is a product of incest, several generations removed. Nevertheless, Ruth the Moabitess does not remain a victim but progresses to becoming a survivor and an important figure in the history of Israel. This despite the fact that Ruth, her mother-in-law

Table 12 Ruth against Antigone

Stage	Antigone	Ruth
1. Precipitating stressor	Antigone is direct product of an unintentional incestuous relationship between Oedipus and his mother Jocasta (Position A)	Ruth is a descendant of an intentional incestuous relationship on the part of Lot's eldest daughter with her father, albeit conducted for a positive reason. (Position B)
2. Reaction	Though raised in a seemingly secure home, Antigone does not seem to be able to separate from her family of origin. She cannot relate to her would-be lover. (Position C)	Though Ruth is widowed at an early age and away from her native land, she does not seem to be enmeshed and indeed is able to bond to her also widowed mother-in-law Naomi (Position E)
3. Response of others	Antigone overidentifies with her family of origin and winds up being buried alive because she will not leave her brother fighting against Thebes to remain unburied. (Position A/C) ₁	Naomi accepts Ruth as her daughter and brings Ruth back with her to Judah and facilitates Ruth's marriage to Boaz, the kinsman of Naomi. (Position D ₁)
4. Effect	Antigone hangs herself, rejecting her would-be lover. Antigone means in Greek against generativity (semen). (Position A/C) ₂	Ruth thrives and becomes a mother of Obed, and ancestress of King David and the Davidic line. Integrates Naomi into her family in a beautiful way. (Position D ₂)

Naomi, and her sister-in-law Orpah are all widowed while “strangers in a strange land,” without male relatives to protect them and thus vulnerable. Indeed, Orpah abandons Naomi and returns home. However, Ruth does not and in one of the most moving speeches in the Hebrew Bible she pledges her loyalty to her mother-in-law: “Whither thou goest, I will go....” (Ruth 1: 16-17).

Naomi accepts Ruth as her daughter and brings Ruth back with her to Judah and facilitates Ruth's marriage to her kinsman Boaz. Yet despite her losses and despite her dysfunctional family history several generations earlier, Ruth, unlike Antigone, is not suicidal, thrives and becomes a mother of Obed, and ancestress of King David and the Davidic line, integrating Naomi into her family in a beautiful way (Ruth 4).

A contrast of these two narratives is presented in Table 12.

Conclusion

Wellisch's previously mentioned clarion call for a biblical psychology resonates with the contrasting representations of hope versus hopelessness in Greek and biblical writings. In the Greek account, Zeus sends Pandora, the first woman, to man (Epimetheus) as punishment for his half-brother Prometheus stealing fire and thus gaining some autonomy. One day, Pandora decides to open the box that Zeus had

sent along with her. The box contained all the evils in the world, which fly out. Pandora closes the lid as quickly as she could, but too late; only hope remains locked in the box, and unavailable to people [87, 88]. Hebrew Scriptures portray hope in a very different way. After the great flood ceases, all living creatures, male and female come out from the ark built by Noah and repopulate the earth through their sexual union. God places a rainbow in the heavens as a sign of His covenant with man that he will not send another flood [89]. The bow becomes the very symbol of hope.

This difference fits very closely our bidimensional approach to Erikson's life stages. The Greek narratives reflect oscillation between enmeshment (A) and disengagement (C). This precludes any healthy development and increase suicidal risk (as reflected in enmeshed, disengaged, and anomic suicides). The biblical narratives, in contrast, promote forward regression on the B- > E- > D axis to the next advanced stage and are truly hopeful and life promoting. Hope is the key to living with purpose and vice-versa. Living with purpose is the key to hope, and our lives are on the line!

Abstract

The term stigma refers to a complex multifaceted social process based on the power that someone exercises over other individuals to devalue, exclude, and marginalize them. It is important to understand the link between stigma and health in order to develop effective public health strategies and to improve mental health in different segments of the populations.

Several studies have shown that the individual perception of public stigma is a major barrier to mental health treatment-seeking.

The insidious nature of stigma influences mental functioning, undermining personal aims. Systemic and widespread negative attitudes and stereotypes toward people with mental disorders are summarized by the term “psychiatric stigma.”

It is important to distinguish the stigma associated with suicidality from the stigma associated with mental disorders. For example, stereotypes and prejudices regarding individuals with suicidal ideation or behavior and individuals with psychiatric conditions have different features. Moreover, recent theories on

Suicide · Psychiatric disorders · Stigma · Discrimination

Introduction

The term *stigma* originates from the Greek language where it refers to signs on the body that expose the moral flaws of the individual. These marks made the person recognizable and allowed the population to avoid him, particularly in public places [1]. The modern conception of stigma is very similar to this, although nowadays it is more related to behaviors and intrinsic conditions than to actual bodily signs. Stigma typically induces emotional responses of dislike and disgust, and even fear, which contributes to perpetuating the stigma and maintaining its social functions [2].

Stigma, prejudice, and discrimination are important factors that lead to health disparities [3]. Therefore, it is important to understand the link between stigma, prejudice, discrimination, and health in order to develop effective public health strategies and to improve mental health in different segments of the populations.

The impact of stigma on suicide risk and mental disorders has recently been acknowledged [4]. However, the term stigma refers to a complex multifaceted social process based on the power that someone exercises over other individuals to devalue, exclude, and marginalize them [5].

The concept of Stigma

Goffman [6] conceptualized stigma as “an attribute that is deeply discrediting, but it should be seen that a language of relationships, not attributes, is really needed; it is considered as a social process and not anymore as an individual attribute.” Goffman noted that stigma manifests itself according to three conditions: “abomination” of the body (e.g., malformations), “tribal identities” (e.g., ethnicity, religion), and “blemishes of individual character” (e.g., mental illnesses). This conceptualization has evolved to refer to a relational construct dependent on attributes that may change in different times and different cultures [7]. Consequently, stigma develops in a framework of social interactions and social exchanges arranged in three dimensions [8]:

- Perspective: how the stigma is perceived by the individual that stigmatizes or by the individual that is being stigmatized.
- Identity: is the stigma related to personal features or it is a consequence of belonging to a specific group?

- Reaction: how do the stigmatizer and the stigmatized react to prejudices and to their consequences, responses that can be emotional, behavioral, or cognitive?

In addition, the mark that causes the stigma has three fundamental characteristics that determine the level of discrimination: visibility, controllability by the bearer, and the impact on people.

Although Goffman [6], in his work, delineated different forms of stigma, he pointed out that the stigma related to psychiatric conditions is one of the most prominent and discrediting types of stigma. Link and Phelan [5] revised Goffman's conceptualization of stigma, specifying that "stigma exists when elements of labeling, stereotyping, separating, status loss, and discrimination co-occur in a power situation that allows these processes to unfold." In addition, Thornicroft [9] shaped the previous definitions by characterizing the stigma as a body of prejudice that represents the emotional response to stereotypes and attitudes that lead to avoidance behaviors. In particular, Thornicroft identified stigma as a process characterized by three domains: the problem of knowledge (ignorance), the problem of negative attitudes (prejudice), and the problem of rejecting and avoiding behavior (discrimination).

In an attempt to categorize the phenomenon of stigma, Reupert and Maybery [10] identified four forms of stigma in the mental health field:

- *Public stigma*, which is inherent in the surrounding population, validates stereotypes and develops discriminative ideas toward individuals with psychiatric disorders. This condition may lead to social isolation, unemployment, and poor social support, and can have an impact on daily activities.
- *Self-stigma*, derives from the internalization of a stereotype, refers to oneself and may cause shame, demoralization, or withdrawal, damaging self-efficacy and self-esteem. This construct has three stages. First of all, psychiatric patients are aware of the stereotypes toward themselves; then they consent to this discriminatory view of themselves; and, finally, they apply the stereotype to themselves.
- *Associative stigma* arises from associating with another individual, for example, the perception of stigma in survivors who have experienced the loss of a loved one from suicide.
- *Structural stigma* includes the government's restrictions on the opportunities possible for people with mental illnesses and the limited options resulting from institutional policies, for example, the lower financial assets allocated by governments to mental health resources that worsen the quality of care of psychiatric patients and the shortage of health professionals willing to work with psychiatric patients.

The behavioral aftermaths of stigma worsen the impairment associated with the presence of psychiatric disorders in many aspects of life (e.g., personal relationships, education, work), limiting opportunities and causing loss of income, unemployment, reduced chances for finding housing, and having access to medical care [11]. Systemic discrimination leads to less investment dedicated

to mental health care compared to physical health care [12]. In addition, psychiatric patients often experience unequal treatment for their physical health conditions that can increase morbidity and result in premature mortality [13]. The barriers that impede access to care result in further consequences for the psychiatric patient, such as delay or refusal of help-seeking and prematurely dropping out of the treatment [14].

Prejudice toward mental illness can also spread to family members and caregivers who may experience feelings of shame, self-blame, guilt, and anger [15]. In societies based on family cohesion, stigma can affect income, work, and marital perspectives [16].

Several studies have shown that the perception by the individual of public stigma is a major barrier to mental health treatment-seeking, especially among young adults [17]. For example, data from National Surveys find that one-third of individuals report that the cause of their decision to not seek treatment, despite perceiving a need, is concern about stigma [18]. In addition, Mojtabai et al. [19] found that one-fifth of individuals in mental health care dropped out of treatment as a result of perceived public stigma. Furthermore, perceived stigma not only represents a barrier to treatment-seeking but can also exacerbate anxiety and depressive symptoms, as well as substance abuse and social isolation [20].

Self-stigma can have behavioral consequences, labelled by Corrigan et al. [21] as the "why try" model, in which internalizing stereotypes about mental illness provoke loss of self-esteem and decrease of self-efficacy, accompanied by behavioral failures. Therefore, stigma may cause disengagement from daily activities otherwise easily achievable or desirable, including personal aspirations. Moreover, this model provides a theoretical framework for understanding how reluctance to obtain appropriate mental health care represents a barrier to accomplishing life goals.

The stigma associated with mental illnesses is often perceived as similar to the stigma connected with racial and sexual discrimination, although the practical consequences may be affected by different factors (e.g., age, self-stigmatization) [22]. In addition, the fear people experience when meeting with individuals suffering from mental illnesses is not only related to the patients' abnormal behaviors linked to their psychiatric conditions (e.g., violence, functional impairment), but also with the labeling process itself. In a study conducted by Thompson et al. [23], respondents reported "loss of mind" as the most disabling condition, but greater knowledge was associated with less-discriminatory attitudes.

Corrigan [24] suggested analyzing "felt stigma" among individuals with psychiatric disorders to ascertain the frequency and degree of stigma that they experience. Corrigan also the examination of three topics:

1. "Signaling events" (e.g., labeling, physical appearance, and behaviors)
2. "Knowledge structures" (e.g., public attitudes about perceived danger and self-care)
3. Pathways that lead from knowledge structures to emotional reactions and behavioral responses

The repercussions of stigmatization are critical for mental health and can also play a role in suicidality [25]. The insidious nature of stigma influences mental functioning, undermining personal aims, obstructing access to higher education, occupation and relationships, and ultimately, jeopardizing general well-being and the empowerment of individuals.

Systemic and widespread negative attitudes and stereotypes toward people with mental disorders are summarized by the term “psychiatric stigma” [26]. Such attitudes are strictly related to discriminatory acts that harm individuals who have psychiatric conditions, directly or indirectly. Some examples, typical of today’s society, include beliefs that mental illness is a sign of inadequacy, deviant behaviors, weakness, poor intelligence, unreliability, and violence [27]. Such beliefs can be found at any level of society, even among individuals with psychiatric disorders [28], and in different sociocultural environments around the world [29]. Corrigan and Watson [30] provided a model that explained the paradox of self-stigma, focusing on the consequences of the internalization of negative attitudes. However, while stigma can affect self-esteem and self-efficacy in some individuals, in others, it can provide energies and cause righteous anger, while some may seem unaffected by it.

A recent review of the literature [31] showed that internalized stigma is strongly and negatively associated with a number of psychosocial variables, such as hope, empowerment, and self-esteem. With regard to psychiatric variables, internalized stigma was negatively associated with treatment adherence and positively associated with symptom severity.

Stigma and Psychiatric Disorders

To better understand the role of stigma in mental disorders, and given the strong link between mental health and suicidality, we will briefly review the effects of stigma on the principal psychiatric diagnoses.

A study investigating suicide and depression showed that American adults believed that recovery for a person with a history of suicide attempts was lower than for a person with mental illness [32]. Moreover, individuals who have directly experienced depression reported feelings of self-stigma, while those who had attempted suicide felt embarrassed and ashamed and wanted to hide their suicidal behavior [33]. In Canada, Mackenzie et al. [34] found that men were more likely to experience public stigma about their depressive conditions than were women. In addition, stigma was greater in younger adults than in older adults. Yokoya et al. [35] analyzed beliefs and discrimination toward suicide and it found that 30% of the participants believed that depression is caused by a weak personality. Only half of the participants believed in the effectiveness of pharmacotherapy for managing depression. These results show that the level of accurate knowledge may influence beliefs and prejudices about suicide and depression.

In patients with bipolar disorders, stigma affects their domestic, social, work, and school environments. These patients experience loss of support, fewer successes, and lower levels of quality of life [36]. In a recent review of the

literature, Ellison et al. [36] found that bipolar disorder is considered more positively than schizophrenia but less positively than depression. Individuals with bipolar disorder reported moderate to high levels of internalized stigma. Regarding overall functioning, several studies have noted that stigma (particularly stigma derived from the internalization of stereotypes) was associated with functional impairment in various domains. Vazquez et al. [37] found that one of the predictors of discrimination in patients with bipolar disorder was their level of functioning; Cerit and colleagues [38] identified an association between stigmatizing experiences and general functioning. Thomè et al. [39] found that interpersonal, cognitive, and leisure functioning were the areas of behavior most strongly associated with stigma, although all the assessed domains showed significant associations.

Individuals with anxiety disorders frequently report the *weak not sick perception*, which refers to the belief that anxiety symptoms reflect personal weaknesses of the patient, and not real medical problems that require treatment and management [40]. Batterham et al. [41] found that perceived stigma was higher in rural areas, and greater exposure to patients with anxiety disorder was significantly associated with increased stigma. Curcio and Corboy [42] reported that rural origins were associated with public stigma, while higher exposure and awareness toward anxiety had a negative correlation with personal stigma. Higher self-stigma was associated with worse treatment outcomes (e.g., low medical adherence, more dropouts, and poor responsiveness). This research shows that stigma has an impact on the management of anxiety disorders, facilitating or obstructing help-seeking and receiving adequate treatment.

Stigma related to schizophrenia is particularly noteworthy. Stigma leads to major negative consequences for self-esteem, social isolation, adherence to treatment, and opportunities to find housing and work or achieving an appropriate level of education [43]. Moreover, stigma increases disability and the burden on the patients and their families [44]. Several studies have shown that schizophrenia is one of the most stigmatized psychiatric conditions [45]. The majority of individuals in the society believes that people with schizophrenia, especially males, are violent and capable of committing dangerous acts against others, especially if untreated. Moreover, those who believe that schizophrenia is due to biological causes have more negative attitudes, while those who have direct experiences with mental illnesses have weaker stereotypes [46].

Several programs have been implemented to address stigma in mental illnesses [47], sometimes considering them as a whole or targeting a single diagnosis (if it is believed that stereotyped beliefs and attitudes are specific for each disorder). The National Alliance on Mental Illness, for example, has implemented anti-stigma interventions in the United States to increase positive knowledge and attitudes toward psychiatric disorders [48], combining psychoeducation and personal contact to boost the efficacy of the program. The promising results have shown the success of contact-based projects in reducing stigma, educating the community, and demystifying the psychiatric conditions through the construction of empathy and intergroup contacts with affected patients [49].

Stigma and Suicidal Behavior

It is important to distinguish the stigma associated with suicidality from the stigma associated with mental disorders [32]. First, stereotypes and prejudices regarding individuals with suicidal ideation or behavior and individuals with psychiatric conditions have different features. For example, individuals who have attempted suicide are thought to be attention-seeking or without a moral sense.¹ For this reason, health professionals must be aware of suicide-specific prejudices in order to deal with them appropriately [50]. Second, in some cases, individuals who have attempted suicide do not have a psychiatric diagnosis [51]. Third, a past suicide attempt may become a crucial and long-lasting part of a person's life, while symptoms of psychiatric diseases may be attenuated, helping the individual to overcome stigmatization. Lastly, different individuals might experience the stigma differently and with different levels of distress and importance [34].

In Australia, Batterham et al. [43] found that about 40% of the sample viewed suicide as an offensive, selfish, or reckless act that should be punished. About 30% of the respondents considered suicide to be indication of weakness, irresponsibility, cowardice, or attention-seeking. In general, Pompili [52] found that suicidal people were labeled negatively as weak and unable to cope with their problems or as selfish. Frey and colleagues [35] found that the highest levels of discrimination toward suicidal individuals were from family members (57.1%) and emergency department professionals (56.6%). Farrelly and colleagues [53] investigated the association between prejudice and suicidality among individuals with mood disorders or schizophrenia spectrum disorders. The results showed that 65% of the sample reported feelings of hopelessness linked to stigma, 38% reported suicidal feelings caused by discrimination, and 20% reported that the experience of stigma had led them to make a suicide attempt. Feelings of discrimination were considered by the patients as stressors that went beyond their coping resources, leading to a negative self-image and a lower perception of support from the social environment. In turn, these perceptions led to feelings of social isolation, hopelessness, entrapment, and ultimately, suicidal behavior.

The interpersonal theory of suicide [54, 55] proposes that suicidal behavior is the result of thwarted belongingness and perceived burdensomeness, that is the belief that one is a burden on others. Therefore, this theory would view stigma as one of the risk factors for suicide since public stigma can cause social isolation, while self-stigma may influence perceived burdensomeness [56]. The stress-diathesis model of suicidality [57] states that biological or psychological vulnerabilities, alongside psychosocial stressors, can exacerbate suicidality. In this model, stigma represents a negative stressor with enduring effects [58]. Furthermore, stigma has a close link with hopelessness, one of the most critical risk factors for suicide [59].

¹ A common myth about suicide is that those who admit to suicidal ideation will not actually engage in suicide behavior. In fact, suicidal ideation and attempted suicide are both risk factor for dying by suicide.

Several research studies have focused on the relationship between stigma and suicidality. Population studies have shown that stigma is less present in regions with lower rates of suicide [60]. In a study of patients with schizophrenia, Sharaf and colleagues [61] found a significant association between suicidality and self-stigma. In a qualitative study, Eagles et al. [62] found that most participants reported that stigma contributed to worsening their emotional state.

Stigma and discrimination are present also in suicide survivors. Suicide bereavement, in fact, is quite different from bereavement after natural deaths and has a strong impact on the suicide's family and friends, with profound consequences that go beyond the immediate loss [63]. In a study of people who had suffered a sudden bereavement, Pitman and colleagues [64] found that relatives and friends of people who died by suicide reported higher levels of stigma, shame, and guilt than those bereaved by other causes of sudden death (natural or unnatural). Moreover, stigma and shame influenced social functioning, help-seeking attitudes, and support offered.

Knowledge of the link between stigma and suicide risk is important for the implementation of effective intervention tactics and strategies. Thornicroft and colleagues [65] have suggested that interventions directed to groups liable to stigmatize suicidal behavior and mental illness (such as employers), together with interventions to manage internalized stigma, may address this issue. Longitudinal studies should address the hypothesis that stigma may be an essential risk factor for suicide, for example, by examining the involvement of the interpersonal theory or the stress-diathesis models of suicidality. Researchers should target the discrimination experienced by individuals at risk for suicide and those with mental disorders, as well as the self-stigma and feelings of shame and, in addition, the consequences of structural stigma on the quality of life and access to mental health services [56]. The mediating effect of depressive symptoms and social rejection and the situational components of stigma should be studied as well as the possible influence of impulsivity [66]. This research could identify the most relevant outcomes of stigma and discrimination that represent risk factors for suicide, informing interventions to reduce the frequency of suicidal ideation and behaviors [67].

Some interventions have already been implemented. For instance, Rogers and colleagues [68] tested the efficacy of two brief, web-based interventions to reduce suicide-related stigma in a sample of students. The first consisted of psychoeducation regarding suicide statistics, risk factors, red flags, and suicide prevention strategies. Participants in the second intervention were assigned to an interpersonal condition in which they were exposed to case studies of suicide attempters with specific details of the attempts, as well as personal stories and interviews about the attempter's life and existential crisis. The two interventions were both effective in reducing suicide-related stigma, and the effect was stronger for those who had previous experiences of suicide. Web-based interventions address stigma issues with cost- and time-effectiveness and can reach a broad range of individuals.

In conclusion, it is important to identify the most common stereotypes about suicide and mental health and assess the impact of interventions to reduce stigma and increase stress coping resources, with the final goal of reducing suicide rates.

Abstract

For some years, suicide rates have been increasing, not decreasing, despite concerted efforts by global agencies and countries' national strategies and innovations in the clinical care of those most vulnerable. In Australia, suicide rates had fluctuated around a slow decline for some years and then began to rise again, reaching the same rate of 12.5 per 100,000 in 2017 as Australia saw 50 years ago (Suicide prevention Australia. Turning points: imagine a world without suicide. 2019, September. www.suicidepreventionaust.org).

Many studies have explored the factors that placed individuals at risk of suicide and global prevention strategies have been based on reducing these risks and building protective factors or addressing specific risks, such as depression, mental illnesses, and other mental health disorders. Research on resilience,

A. M. Chauvin (✉)

e-mail: a.chauvin@griffith.edu.au

however, has only been emerging in the suicidology literature over the last decade, yet there is much that can be learnt from those who have been resilient in the face of adversity, whose lives were often characterized by risk and vulnerability but who navigated a path to eventual well-being, even flourishing.

There has, however, been extensive research into those who have been resilient in the face of trauma, which has been building since World War II. This chapter provides an abridged review of this 80 years of research into resilience for the contribution it could make to innovation in suicide prevention and better support recovery and prevention of relapse after suicidality or suicide attempt.

Keywords

Resilience · Lived experience · Suicide and resilience · Resilient survivors, Suicide prevention

Introduction

Research and interventions for suicide prevention, have usually been based on what we know about the risk factors leading individuals to attempt or complete a suicide based on retrospective studies of attempted and fatal suicides. This continues to be a key focus in suicide prevention research, and significant investment continues to be made in the establishment of suicide registers across the globe [57]. Although this line of questioning has been useful, it has overlooked the valuable information that can be gained from the lived experience of those who have suffered extraordinary trauma and/or deprivation to understand how they survived, did not succumb to suicidality, and instead navigated a path to eventual well-being and even greater resilience to future adversity.

This chapter explores the evolution of research into resilience, through its growing links with the contemporary contributions of related disciplines such as positive psychology and innovations in working with neuroplasticity. What did vulnerable individuals do to stabilize and recover, and what resources did they draw on that could inform our population-based suicide prevention strategies and clinical treatment practice?

Learning from Resilient Survivors and the Contribution This Can Make to Suicide Prevention

Exploring resilience to understand how some or all of its elements might be applied to suicide prevention has only begun to emerge in the suicidology literature over the last decade and is now beginning to gather momentum, with studies exploring the role of positive thinking [42]; connection with others as a buffer [55] and the role of self-efficacy and spiritual well-being in recovery from abuse and subsequent suicidality [33]. There have also been population-specific studies appearing, such

as an exploration of the increased resilience of Alaskan and American First Nations elders compared to their youth [47].

One of the most significant recent efforts to systematically understand the elements of resilience and find ways to apply this knowledge to programs to build resilience has been undertaken by the US military in collaboration with the National Institute of Mental Health to reduce the risk of suicide [43, 48]. Referred to as the Army Study to Assess Risk and Resilience in Service members (Army STARRS [www.armystarrs.org]) it comprised an initial multicomponent epidemiological and neurobiological study of risk and resilience factors for suicidal thoughts and behaviors from 2009 to 2014 and a longitudinal follow-up STARRS – LS from 2015 to 2020.

Using a combination of administrative records of over a million personnel; representative surveys of over 41,000 soldiers; pre- and post-combat surveys of more than 10,000 combatants; case-controlled studies of 186 hospitalized suicide attempters and 375 controls; computerized neurocognitive tests; and blood samples, the study captured the complex interaction of environmental and genetic risk and protective factors and varying settings and contexts. It also highlighted the importance of the person's life and career history in relation to suicidal thoughts and behaviors.

Systematic analysis of this data to understand the modifiable psychosocial, epidemiological, and neurobiological risk and resilience factors for suicidal thoughts and behaviors is ongoing and to date has had a focus on risk identification and screening for vulnerability, e.g., experience of violence in childhood, traumatic brain injury, failure to feel connected to one's unit, and perceived burdensomeness [10].

There has also been an effort to understand the characteristics of personnel who have been through years of imprisonment, solitary confinement, and torture to understand how they remained (and remain) resilient (Southwick and Charney [56], and over time other helpful concepts are emerging from these studies, such as the mindset, which contributes to post-traumatic growth, which can mitigate the risk posed by post-traumatic stress disorder (PTSD) [38].

As interest in resilience builds in the suicidology research community, most recently, there has been a concerted call by a global consortium of suicide prevention researchers, for a shift from the heavy focus on risk analysis to research on how to build resilience for the value it might provide in the prevention of suicide [30]. Their literature review of 695 peer-reviewed articles suggested that very little research on resilience exists specifically in relation to suicide prevention, although they did identify research on individual factors that confer resilience and could contribute to suicide prevention. Ivbijaro et al. [30] asserted their findings indicate the merit, which biopsychosocial interventions might have for building resilience as a mitigator of suicidality and recommended the further investigation of such.

While the concept of resilience has been gaining a foothold in suicidology research over the last decade, there has already been a large body of research on resilience, which has been growing since World War II. While the focus of this research has not been specifically on its value in suicide prevention, there is a wealth of material that could inform suicide prevention strategies and clinical practice, which has yet to be fully drawn upon. This chapter scans the resilience research of

the last 80 years for its value in prevention, early intervention, stabilization during acute suicidality, and to inform recovery after suicide attempts and prevention of relapse into suicidality.

The Evolution of Research on Resilience

One of the earliest and most seminal works on resilience was Viktor Frankl's study of fellow inmates in Auschwitz [21]. On arrival at the death camp, this eminent psychiatrist decided that if he was going to survive he would need to understand the attitudes and behaviors that were characteristic of those who did survive and of those who more rapidly deteriorated and died.

For Frankl, a critical factor that seemed to be at work was the meaning a person gave the traumatic experience. For example, negative religiosity (e.g., "I am being punished") or anguishing (e.g., "why me?") appeared to prompt a downward spiral. On the other hand, positive religiosity (e.g., "I am being tested") or a determination to live (e.g., "I will not let them win – I will survive and I will find my wife and children") appeared to support people to survive. He observed that it was those who comforted others and gave away their last piece of bread who survived longest. He concluded that everything can be taken from someone but the last freedom – they can always retain the freedom to choose how to respond to the situation they find themselves in.

Viktor Frankl chose to take the stance of objective observer, fueling his determination to survive by focusing on his desire to teach others what he learnt from his experiences in Auschwitz. During his darkest days, he describes how he imagined himself giving lectures to large audiences about his findings, and after the war he did, indeed, go on to do just that.

Frankl's approach was a major departure from the dominant notion that resilience was a trait that some people had and others did not. Frankl had made a decision to learn how to think and behave resiliently. On his release, Frankl returned to Vienna, where he completed development of Logotherapy, an existential approach to psychotherapy, which underpinned what is referred to as the third Viennese School of Psychotherapy. In 1946, Frankl published his now-famous book, *Trotzdem Ja Zum Leben Sagen: Ein Psychologe Erlebt das Konzentrationslager* (*Saying Yes to Life in Spite of Everything: A Psychologist Experiences the Concentration Camp*; now referred to as *Man's Search for Meaning*).

The meaning we give life and events in our lives has remained one of the elements that are consistently cited in research on resilience – having a framework of meaning through which to filter adversity and/or a perceived purpose in life, a reason to persevere and survive through hardship or duress [56]. Meaning certainly played a pivotal role with the individuals who shared their lived experience of recovery and building resilience, as described in the next chapter [9]. An important variant for these people though, perhaps similarly to Viktor Frankl, was the capacity to be resilient when all meaning has collapsed and to find comfort in stripping back the beliefs that had supported them to date and searching for or constructing new meaning on which to build a way forward [7, 8].

Longitudinal Studies of Resilience: What Determines Someone's Trajectory in Life?

Research on resilience as a concept in its own right began in earnest in the 1950s when Garmezy and Rodnick [24] sought to understand the heterogeneity of individuals who developed schizophrenia and found that taking premorbid adjustment into account reduced the variability between patients. This stimulated them to begin exploring their premorbid good or poor adjustment. As studies to date had depended on the adequacy of, or inferences made from, case history records, they commenced prospective studies, initially focusing on the traits of children growing up at high risk of schizophrenia or with parents with schizophrenia to understand positive adaptation from a developmental perspective for its contribution to clinical considerations.

These studies expanded over the following two decades, beyond study of the characteristics of the children themselves to also include consideration of external risk and protective factors, such as family and broader social environments. This included examination of the biopsychosocial and environmental factors that may have led to good or poor premorbid adjustment, with an examination of the trajectory of children growing up in poverty, to identify the factors that promoted greater resilience and reduced risk of pathological or other negative outcomes [23].

This burgeoning interest led to wide-ranging studies of normative and high-risk young people to understand what underpins the competence and positive adaptation that might mitigate potential psychopathological outcomes [40].

The interest in the factors that contributed to resilience in children growing up with high-risk parents and/or environments led to a proliferation of studies, but the field suffered criticism that the capacity to generalize was reduced by a lack of consistent definitions and rigor in the studies [35].

Systematization of research in resilience was brought to bear in perhaps the most famous longitudinal study undertaken by Werner and Smith [59, 62], examining a cohort of 698 children from birth in 1955 and tracking them as they grew up in poverty on the island of Kauai, Hawaii, through to their third decade of life. One-third of the cohort were designated as being at high risk of a negative life trajectory because of the poverty and dysfunction of the families into which they were born and, indeed, two in three of these high-risk children did develop serious learning or behavioral problems by the age of 10, and by the age of 18 years, delinquency, mental health problems, and/or teenage pregnancy were common. One in three of these children, however, grew into competent caring adults.

This study found that these "invulnerable" children had experienced less separation from their mothers in the first year of life, were perceived by others as being easy company and good-natured, received a great deal of attention from others, and knew how to get attention when they needed it. By 18 years of age, they had developed a positive self-concept and internal locus of control, in contrast to the other children, whose trajectory was toward high-risk behaviors and mental health problems [59, 62].

Some of the lessons learned from this group of children may still infer inherent characteristics, such as an easy temperament, which may naturally attract positive

attention. Other elements of resilience could have been attributed to good luck, e.g., with fortunate circumstances, such as less separation from their mothers and where the increased presence of the mother inferred a level of attentiveness, which consistently appeared as a mitigating factor, providing consistent support over time. There were also, however, other factors that enabled resilience to grow and that could potentially be learnt.

The internal locus of control, which resilient young people developed, knowing how to get positive attention when needed and a positive self-concept could have been the result of the preceding factors interacting to build positive self-regard. Adoption of an internal locus of control, however, may also reflect a resilience factor, which can be learnt.

Importantly, the individuals Werner studied were able to develop resilience even when they had not appeared to be on a positive trajectory. By their 30s, the majority of those who had experienced adverse outcomes in adolescence had returned to their education, ceased self-destructive behaviors and found employment. Only 18% were described as troubled adults, with serious coping problems. Werner described how a “chain of protective factors linked across time, afforded vulnerable children and teenagers an escape from adversity and contributed to positive outcomes in their adult lives” ([59], p. 508).

In the 1970s, Garmezy and Rodnick commenced a 20-year longitudinal study of children growing up in highly stressful environments, referred to as the “Project Competence Longitudinal Study” (cited in [23], p. 265). They sought to understand why some children were still able to progress through normal development [23] and identified the influence of both internal and external factors, such as “average or above average socioeconomic resources, cognitive skills, openness to experience, drive for mastery, conscientiousness, close relationships with parents, adult support outside the family and feelings of self-worth” ([41]; Masten and Tellegen, 2012, cited in [23], p. 265).

The findings of these longitudinal studies generated inquiry into the range of risk and protective factors, which might predict the trajectory of a young person and which could perhaps be manipulated positively. His analysis identified pivotal risk/protective factors, “internal factors included personality, advanced motor and language skills and self help skills. External factors included family and community” (Werner and Smith [61], cited in [23], p. 265).

Werner and Smith had found that it was important for the child to establish a close bond with a competent emotionally stable person in the family from an early age, someone who was sensitive to their needs, such as grandparents, older siblings, or others. However, if their family was dysfunctional, it could be just as effective and important for someone from the community to fulfill that role. This person could be a neighbor or some reputable figure such as a church member, school teacher, head of sports or other association, or other elder mentors (Werner and Smith [61], cited in [23]).

Werner [59], in reflecting on the Kuai longitudinal study, identified clusters of protective factors, which contribute to resilience, including (i) a temperament that elicited positive responses from a number of caring people; (ii) skills and values that motivated them to make good use of what strengths or opportunities they had; (iii)

parenting that fostered self-esteem in these people; and (iv) supportive adults who acted as “gatekeepers of the future,” e.g., grandparents, older siblings, or the “surrogate parents” from the community, referred to above, who could act as mentors.

Werner and Smith’s longitudinal study provided the earliest systematic analyses of risk and protective factors, and these factors can be seen in the variations of Risk and Protective Factors Frameworks, which have been adopted by many of the countries, which have responded to the UN and WHO’s call in 1993 to mobilize national suicide prevention strategies [11–13, 63].

It has not been possible, however, to evaluate the effectiveness of the application of the risk and protective frameworks and the national suicide prevention strategies that they underpin as it is impossible to know how well these national strategies have been implemented [63]. Suffice to say, suicide rates not only remain high but are increasing in many parts of the world [57, 64].

Another key contribution of Werner and Smith’s study was recognizing “*the opening of opportunities at major life transitions, from high school to the work place, civilian life to military life, from single to married, the arrival of parenthood*” ([59], p. 508). This finding highlighted the windows of opportunity that exist where people are demonstrably more open to self-reflection and learning when interventions, which teach new life skills, might find receptive ground. In line with this finding, many national suicide prevention strategies have targeted people in life transitions, such as early adolescence and school-leavers, seeking to capitalize on the curiosity that accompanies new chapters in life [12, 13].

Perhaps the period post-suicide attempt is one such window of opportunity where the person may be open to self-reflection on their strengths and on the areas of vulnerability that led to their suicidality and learning how to address these risks to prevent any future decline/relapse?

Resilience as Dynamic and Always Evolving

For many years, there had been an ongoing debate about whether resilience reflects stable, measurable traits or is a dynamic process in which resilience can develop at any point in time in life [4, 30]. It has taken some time to arrive at a definition of resilience, which allows for the possibility that resilience could be developed. While resilience was initially regarded as a singular character trait, however, it has now come to be seen as a collection of character traits, ways of thinking and life skills, and a recognition that these can be developed at any time in life and may be able to be taught [1, 46, 54].

Ahern [1] described how there had been a shift toward a systems theory definition of resilience, which considers both the elements of resilience, which may reflect inherent characteristics or capacities, that could be described as a trait and the resilient behaviors and ways of thinking that can be learnt. The findings in Werner and Smith’s longitudinal study, that those on a negative trajectory could by their 30s build skills and make choices, which resulted in them ceasing destructive behaviors,

becoming employed and going on to thrive, support the systems theory of resilience, that resilience is dynamic and always evolving [20, 59].

Systems theory also adds to this, though, that the elements of resilience in a person's repertoire can impact upon or be impacted upon, positively or negatively, by biological, social, and environmental factors. For example, the neurochemistry of depression, anxiety, post-traumatic stress disorder (PTSD), or the fatigue of a chronic illness could undermine the level of resilience derived from traits and from ways of thinking. Conversely, learned skills and the development of the behaviors of a resilient person can positively affect biology and neurophysiology, such as the positive neurophysiological, functional, and neurochemical changes that fMRI and other studies have demonstrated are generated by activities, such as meditation [16].

This speaks to the need to work with people holistically to consider physical health and psychological health, optimize positive social connections, and address the health of their environment.

Most recently, studies in resilience have shifted to explore how resilient thinking and/or behaviors might actually work with neuroplasticity to embed new automatic responses to adversity at the deepest level in the person, e.g., stabilizing the hyper-reactive amygdala of people with post-traumatic stress disorder (PTSD), thus mitigating the psychological and neurophysiological impact of trauma [14, 49, 54, 56].

The capacity to work with neuroplasticity has added weight to the possibility that people could learn simple techniques to use as tools in self-managing recovery from depression and suicidality and that could contribute to building resilience. There is now a large body of hard evidence that as elements such as insight and life skills develop, these contribute not only to improved life choices but also lead to changes in brain functioning and the consequent neurochemistry, which mitigates depression, anxiety, and suicidality [14, 16, 28, 54].

What this means for suicide prevention interventions has yet to be explored. While systems theory has identified the types of factors, which might interact when a person responds to adversity, there does not appear to be much research on how resilient people manage and/or apply the resilience factors they possess for better or worse effect. Despite the research recognizing that resilience factors accumulate and build on one another or can act as springboards to greater insight, motivation, and further development, there is still a need to investigate the underlying process by which protective factors are brought together by a person and used when they face adversity.

Galatzer-Levy, Huang and Bonanno [22] emphasize the importance of moving away from a binary definition of resilience to considering trajectory models when considering responses to stress and trauma as a greater understanding of these can inform identification of state and trait risk factors and potential interventions. Galatzer-Levi et al. describe how trajectory models consider the resilience of those minimally impacted by trauma, those who take longer to recover but do not develop chronic PTSD, those with delayed onset stress disorders and chronic stress/PTSD, and then teases out the heterogeneity within trajectories to understand the implications of the biopsychosocial factors of the individual, their developmental stage and coping ability, the context and nature of the trauma, and whether the trauma is a

single event or repeated. Their review showed a proliferation of studies seeking to understand the complexities of resilience and recovery but highlighted that this field is in its early stages of development. It is likely that this is where participative research with those who have lived experience of recovery, prevention of relapse, and building resilience becomes important.

Post-Traumatic Growth

A recent study of military veterans explored post-traumatic growth for its capacity to mitigate the impact of trauma and reduce suicide risk [38]. It found that individuals experiencing post-traumatic growth did not just return to their pre-trauma baseline of resilience, but instead developed beyond pre-trauma levels in one or more domains of their life. The growth that emerged from their struggle to cope with their distress and reassess their worldview was found to have changed self-perception, improved relationships with others, increased emotional expressiveness, and generated a heightened sense of spirituality and sense of meaning to life. While this did not necessarily reduce their PTSD, their greater appreciation and enjoyment of life meant their distress now coexisted with increased quality of life. As Seligman [54] explains, a state of well-being can form the foundation from which a person moves from survival to flourishing.

These findings support the argument that slower recovery may still reflect resilience as the person does eventually overcome the psychological impairment, reflecting great, or perhaps even greater, strength than those who bounced back quickly [38, 65]. Some say this post-traumatic growth reflects even greater resilience as their existential struggle to cope, recover, and move forward develops strengths greater than those with which they began.

This is important in consideration of suicidality. It could be inferred that a suicidal person is not resilient; however, it may be that the suicidal person has suffered multiple challenges, which have temporarily left them overwhelmed and psychologically impacted upon but that they are able to refocus and recover and become resilient once more or even more resilient than before [38, 65].

Having survived trauma and gone on to live well builds the confidence to approach future adverse events as a problem to be solved with the knowledge that one has had the capacity to do so before [4]. How one views adversity makes a critical difference – is it seen as trauma that can crush you or a challenge to learn and grow?

Can those Who Are Not Resilient at the Time of Greatest Vulnerability Build Resilience?

Masters and Naryan [39] described children who were liberated from concentration camps, who had initially suffered the greatest traumatic impact because of being separated from their parents. They go on, however, to describe that on longitudinal

follow-up even these orphaned children were able to make a strong recovery and go on to thrive. This harks back to Werner and Smith's finding that slower recovery because of initial psychological impairment does not reflect a lack of resilience. Rather, the person did ultimately demonstrate great resilience in finding the resources to rebound from that initial longer impact, their struggle resulting in the post-traumatic growth supportive of recovery and going on to thrive [38, 65].

Masters and Naryan [39] point out that these orphans showed great resilience even though they retain psychological scars. *"This mixed picture of resilience and lingering vulnerability or harm from extreme and prolonged trauma has continued to characterise the findings on children who survive the horrors of war, including cases of rescued child soldiers"* ([39], p. 229). As Seligman [54] similarly explains, developing the factors that contribute to resilience and an improved feeling of well-being does not infer never feeling sad. It infers developing a pervasive sense of well-being and realistic optimism, which provides the capacity to sit comfortably with, and reflect upon, sadness, loss, and adversity and have resilience in the face of these. This echoes the state of coexistent resilience and vulnerability, which was found in survivors of war, and has been seen in children and young people, who are survivors of abuse [39].

The examples of the war orphans and the experience of military personnel who experienced great harm but were ultimately able to recover and go on to thrive are important to note, both for service providers working with vulnerable populations and for the hope it can give those populations who are suicidal as a result of great trauma. Knowing recovery and flourishing are possible in those who are similarly survivors of prolonged violence and abuse, natural disasters, refugees fleeing armed conflict, military personnel, and other frontline professionals awakens hope. Being made aware of examples of the strong recovery of others who have been through trauma can remind individuals of how they, similarly, have recovered from trauma in the past, reassuring those who are still vulnerable and may have lost confidence in their own resilience.

Vulnerability, scars, do not equate to weakness or to lack of resilience. Even for individuals who have survived extremely prolonged trauma and loss, there is the demonstrable possibility to recover and thrive [21, 39], to experience a quality of life, which mitigates ongoing mental health distress and may reduce suicidality [38].

Building Resilience in Individuals to Better Prepare Them for Life's Adversities

The most extensive studies of the roles of risk and resilience in preventing suicide to date have been those undertaken by the US military, aiming to understand biopsychosocial determinants of risk and resilience. This has been in order to build an approach to training military personnel to be more resilient in the face of trauma and reduce the incidence of suicide in the armed forces [43, 48].

Systematic analysis of this data to understand the modifiable psychosocial, epidemiological, and neurobiological risk and resilience factors for suicidal thoughts

and behaviors is ongoing but to date appears to have had a focus on risk identification and screening for vulnerability, e.g., experience of violence in childhood, traumatic brain injury, failure to feel connected to one's unit, and perceived burdensomeness [10]. However, findings, such as Southwick and Charney's [56] identification of the elements of resilience found in veterans who survived years of solitary confinement and torture after capture and Martz et al.'s findings, outlined above, on the mindset, which can support post-traumatic growth in veterans [38] suggest the STARRS and STARRS – LS studies may yet reveal insights that can helpfully inform broad population health promotion strategies and targeted interventions to build resilience in individuals at risk of depression and suicidality, especially where trauma is one of the potential triggers.

Southwick and Charney [56], in their work on the characteristics of veterans and others who were resilient survivors of great trauma, reviewed the resilience research from a range of perspectives, including biological, social, psychological, and spiritual. They interviewed resilient survivors, such as veterans of the Vietnam War, who had been tortured and imprisoned in solitary confinement for many years and civilians who had survived trauma, such as kidnappings, rape, and attempted homicide to understand why *"some people not only survived enormous stress and trauma, but had somehow endured or even thrived"* ([56], p. 7). They found that the following resilience factors consistently emerged:

- Realistic optimism (the person reminding themselves of evidence of their survival of past trauma).
- Facing their fear with an adaptive response.
- A moral compass, an ethical framework for making decisions when under duress – *"What is right."*
- Religion and spirituality – drawing on some kind of faith, beliefs, and/or practices.
- Social support – finding ways to proactively connect.
- Role models – having had or identifying role models, who provide a road map.
- Training – physical fitness and building strength.
- Brain fitness – challenging the mind and heart.
- Cognitive and emotional flexibility.
- Meaning, purpose, and growth.

Globally, in programs for recovery from natural disasters and in the rebuilding of communities after armed conflict, researchers have for some time sought to explore whether constructive skills such as these can be built during childhood and adolescence to support the young people to develop greater resilience in the preparation for traumatic events of this scale.

Programs such as these have used successful exposure to moderately stressful experiences to develop coping mechanisms as moderators of traumatic impact in situations of mass trauma, such as natural disasters and war [17]. These programs aim to build what they describe as *toughness*, as well as other resilience factors. The assumption is that developing toughness can act as a buffer to trauma and aid

recovery, thus reducing the risk of fatigue and anomie, which increase the risk of suicide [5, 38, 50, 52]. Southwick and Charney [56] found that stoicism played an important role for the military personnel they interviewed who were resilient despite years of solitary confinement and torture.

Martin Seligman [54] has described *grit*, perhaps similar to toughness, as one of the strengths, which contributes to well-being. He describes it as reflecting another form of intelligence, perhaps similarly to the differentiation between academic, emotional, and social intelligence, concepts that Daniel Goleman [25] introduced and that provided an entirely new language for reflecting on personal strengths and refining the foci for personal development. Seligman [54] has piloted the reconfiguration of curricula in schools, such as the Geelong Grammar School Project, to integrate development of the strengths that underpin resilience into lessons and through design of school activities that foster the development of grit. He explains that the capacity to learn is not only based on intellect but on a character that is willing to push on when feeling daunted or fearing inadequacy and potential failure.

It is possible this grit and determination would be even more important when the stakes are highest, when fear of failure or perceiving previous failures as a sign of a personal flaw leads to a collapse of confidence rather than being seen as just another opportunity to learn. Camus [6], in his essay on suicide, *The Myth of Sisyphus*, said, “The instant when the mind opts for death infers ‘*confessing that life is too much for you and you do not understand it*’ . . . (or) *merely confessing that ‘it is not worth the trouble’*” ([6], translation by Justin O’Brien, p. 4).

There is a wave of recent literature that is challenging the notion that depression is solely a problem of chemistry, which can be effectively treated pharmacologically [5, 28]. Bastian questions whether we have begun to be so protective of children that we are creating “soft” generations, so protected from the risks children used to encounter, e.g., in adventurous outdoor play after school, and so sensitized by society’s efforts not to offend them, “*cottonwooled*,” that they have not developed and practiced toughness.

It is important to understand that the toughness Bastian suggests is not just about internal fortitude but is also tied to having a capacity to reach out for support and exercise reflection, problem-solving, and self-care practices while navigating a path through life’s challenges. Toughness does not infer or suggest people hide their distress and act tough.

Studies on whether someone perceives adversity as a threat or a challenge suggest that people can become skilled at weighing up the threat at hand against their personal and external resources [50, 51, 53]. People can perceive adversity as a challenge if they believe they have the resources to proactively meet that challenge or conversely they can perceive adversity as a threat if too many factors are out of their control or perceived to be out of their control [50, 51]. This finding supports the notion that when adverse events occur a positive self-appraisal is a buffer to hopelessness, depression, and suicidality [45].

This personal assessment process generates a reevaluation of the magnitude of the threat, in the light of the personal resources the person has at their disposal and

therefore how trapped within the situation the person feels they are [31]. Perhaps programs to build toughness, such as those described above, can also contribute to improved positive self-appraisal and the buffer this may provide to suicidality [45].

Indeed, if one looks at the breadth of the resilience literature, evidence clearly suggests that people can build on their dispositions, such as temperament, health, and intelligence, and make best use of their context, e.g., familial, community, moment in time, social and cultural setting, and can develop the ways of thinking, behaving, and ability to identify and tap into resources, which build their resilience. Protective factors can be built to increase the chances of creating a resilient response to adversity, creating a positive trajectory in the face of adversity or after experiences of great trauma [52, 53, 56, 59]. This would in turn reduce the risk of a decline in suicidality.

Considering the likelihood that most people even in peacetime will encounter traumatic events, such as domestic violence, gender-based violence, violent crime, bullying, accidents, and, as we have seen with COVID-19 – illness, loss of loved ones, and/or loss of home and dislocation, it makes sense to prepare children from an early age with the attitudes and skills, such as compassion, connectedness, curiosity, and a solution focus, and opportunities to practice these. Evidence suggests that the opportunity to succeed against challenges could build the confidence in their ability to deal with adversities that foster evidence-based optimism and an internal locus of control [54].

Choosing How We Respond to Distress, Trauma, and Depression

Southwick and Charney [56] described how the resilient survivors of great trauma, whom they had interviewed, had accepted responsibility for their own emotional well-being, even while the traumatic experience was occurring, and chose to use their experience as an opportunity for personal growth.

This reframing of distress as an opportunity to grow takes us back to Viktor Frankl's experience and his observations in Auschwitz, *"Everything can be taken from a man but one thing: the last of the human freedoms—to choose one's attitude in any given set of circumstances, to choose one's own way"* [21].

Johan Hari [28] has also more recently reminded us that depression may have an evolutionary purpose: that depression can be a trigger for reflection on what is working and what needs to change in life. Hari describes the need to address what he describes as *lost connections*, e.g., with meaningful work, relationships, and values. He explores the impact of trauma – the loss of hope in a secure future and how depression can mobilize an individual to choose growth, to make a proactive change to a more positive life trajectory, especially if they are supported to do so.

For example, depression in response to oppression, bullying, and family violence may be a normal response to distressing circumstances and function as the catalyst for the person to seek help and/or seek a path away from the destructive circumstances and/or environment [27]. In these instances, depression may be pointing to a need for referral to interventions and support to address the cause of distress while

also providing support to address the mental health impact of the distress with which they have been living. Suicidality is complex and needs a multidisciplinary response, not simply the medication of distress without addressing the source of the distress.

This suggests a different kind of engagement with individuals in distress, suffering from depression, to that which has been pursued to date, that is, the suicide prevention strategies that have focused on encouraging individuals to seek help through primary health-care providers. The original intent of these strategies was to provide easy access to help through a general practitioner who could then be able to refer the person to mental health professionals for assessment and therapeutic interventions.

This strategy has been problematic though as there has been and still is a significant worldwide shortage of mental health professionals and mental health services to whom people at risk can be referred by a general practitioner [3, 29, 44, 60, 63]. Waiting lists are long, and often only acute cases, those who have just attempted suicide, can be prioritized for intervention [8]. Perhaps the shortage of mental health professionals to whom people at risk can be referred is a contributing factor to the continually rising suicide rates?

This problem had already begun to emerge more than a decade ago, and, with no immediate resolution to the mental health workforce shortage in sight, suicide prevention specialists had called for research that can contribute to the development of methods to enable greater self-management of and recovery from depression, including identification or development of tools and supports that can be provided for those who are vulnerable, to reduce their risk and begin their recovery from suicidality [29]. It may be, however, that research that would enable self-management of depression and prevention of the slide into suicidality has been going on in fields parallel to suicidology, building a body of evidence-based techniques that stabilize the individual in acute distress, support reconnection with strengths, enable safe reflection on vulnerabilities, and analysis of how these may be addressed.

Working with Neuroplasticity: Great Cause for Optimism

It is perhaps studies on neuroplasticity that offer the greatest cause for optimism in suicide prevention. There is now a significant body of evidence through fMRI and other indicators, which demonstrates how we can work with neuroplasticity to reshape the brain, its neural wiring, functioning, and the cascade of related neurochemistry, to address a range of distressing conditions, including depression, post-traumatic stress disorder (PTSD), and other risks for suicidality [2, 14, 18, 19, 26].

As early as the 1970s, Daniel Goleman, Richard Davidson, and Jon Kabat-zin were hypothesizing that meditation might work with the brain to generate positive mental states, which might in turn have possible therapeutic applications. The problem was that the only measures they had available were the relatively blunt instruments of self-report, electrocardiograph (ECG), and blood and urine tests looking for changes in markers like cortisol [15, 16, 26].

Nevertheless, the possibilities for the application of meditation in psychotherapeutic contexts captured the imagination of researchers and evidence began to build. Kabbat-Zinn [32] developed mindfulness-based stress reduction (MBSR) therapy at the University of Massachusetts Medical Centre, a program with demonstrable success in pain management for palliative care and treatment of chronic illnesses. Based on the success of this approach, the Centre for Mindfulness in Medicine, Health Care and Society was established in 1995. In his text, *Full Catastrophe Living*, Kabbat-Zinn [32] reflects on records of having treated over 18,000 people using the MBSR program, not only promoting well-being for people, but relief from distress associated with chronic and other illnesses, which had previously been without relief.

Also in 1995, Teasdale, Segal, and Williams, at Oxford University, developed mindfulness-based cognitive therapy (MBCT), with a particular focus on the use of mindfulness meditation to prevent relapse in depression. The findings were remarkable, with relapse to depression cut by 50% for individuals who had previously been resistant to a range of treatments, including drugs and electroshock therapy (ECT). These studies suggested great promise but had not included a control group and so rigorous trials using an active control were undertaken, this time led by Williams, who engaged 300 participants suffering from severe depression, all of whom were prone to relapse despite medication. They were assigned randomly to MBCT or two other control groups: either learning basic CBT or a session with a psychiatrist as usual. The study again demonstrated the efficacy of mindfulness in reducing relapse into depression and was found to be particularly useful for patients with a history of childhood trauma. Further, a year later MBCT was still proving effective in preventing relapse [26, 66].

Goleman and Richardson [26] describe how a European research group then replicated the study with randomized control groups and again found that MBCT was an effective way to reduce relapse in depression in individuals for whom medication had not worked. They describe Segal going on to use fMRI to explore the reason for MBCT's effectiveness and that he found the patients with 35% reduced relapse had a greater increase of activity in the insula after mindfulness practice.

In the context of the MindScience dialogues, convened by Harvard University (His Holiness the Dalai Lama, Benson, Thurman, [34]), His Holiness the Dalai Lama had committed to encouraging highly skilled practitioners, monks with thousands of meditation hours, to make themselves available for a series of studies to understand the range of potential changes possible through different meditations. The capacity to use fMRI to actually see the different types and areas of impact, which different meditations made, was groundbreaking. By 2003, Richard Davidson and colleagues were undertaking studies at the Waisman Laboratory for Brain Imaging and Behavior at the University of Wisconsin-Madison, working with the first one and then a number of Buddhist monks in the Tibetan tradition, using fMRI to understand the impact of different meditations on the brain [26].

In these early studies, they explored a range of meditations, including mindfulness and meditations to generate compassion, such as loving kindness meditation.

Researchers observed that different meditations work with different parts of the brain. Mindfulness works well to stabilize and improve affect regulation and was found effective in reducing depression. Loving kindness was also very effective in reducing depression and found to be particularly effective for individuals with post-traumatic stress disorder, its activation of areas for the frontal brain also impacting on the activity of the amygdala, reducing the hyperreactivity that can contribute to frequent fight, flight, freeze submit responses, and the potential consequent cascade of neurochemistry, characteristic of depression and anxiety.

Over ensuing years, Davidson and colleagues were able to work with 21 monks to understand what the impact of long-term meditation is on the brain, with findings from these studies suggesting that practicing meditation for thousands of hours actually altered the structure and function of their brains, transforming the states generated in meditation into enduring traits [26, 36].

Davidson was curious whether this effect could only be achieved by an experienced meditator, like these monks, or whether there may be benefits for others and explored whether the changes they had observed were only possible with years of practice or could be achieved with naive meditators and whether the changed states created by meditation would over time change the structure and function of the brain and become traits, embedding new ways of functioning and responding to adversity and/or could be used to address problems such as depression, anxiety, and PTSD [26].

Years earlier they had found that meditation practice can have a positive effect within weeks, e.g., with meditations based on compassion seeming to settle the hypervigilant amygdala [36]. Studies since that time have shown that compassion-based meditation is particularly useful for trauma and individuals who suffered trauma in childhood [26].

As the number of fMRI studies on meditation grew, it became apparent that different meditations act on the brain in different ways and so studies need to be specific about which meditation practice is under investigation [36]. A number of systematic reviews, however, have also noted that many studies continue to be exploratory in nature and that there needs to be more use of rigorous designs using active control groups to confirm the veracity of the promising results to date [26, 37]. Having said that, significant ground has been made applying promising meditation techniques in clinical practice, with consistent positive results also contributing to the building of evidence-based practice.

Neuropsychiatrist Jeffrey Schwartz, of the University of California, had worked extensively with people suffering from obsessive-compulsive disorder (OCD). It seemed that people with OCD suffer from hyperactivity in the orbital frontal cortex (which generates the feeling “Something is wrong here,” flagging a risk that must be addressed); and the striatum (hypothesized to link actions with rewards, which normally would recognize when remedial action has been undertaken, e.g., hands washed to address the threat of germs) ([49], p. 67) and close of the threat warning.

Schwartz decided to take a neuroplasticity-informed approach to understanding and treating OCD. He hypothesized that OCD was the result of the frequency with which attention is given to the alert – danger signal as this would result in

myelination of the pathways involved. He hypothesized that this would result in new warning signals arriving so fast – e.g., Germs! Wash your hands! – before the striatum could reward the last hand wash and reassure the person that the germs had been dealt with. The speed with which warnings were arriving was preventing the message that the threat had been averted from arriving, before the next threat message did. He described this repeated, seemingly unbreakable circuit as brain lock [49] and suggested that traditional therapies, such as exposure and response prevention (ERP), might even exacerbate the problem by continuing to give attention to the threat message.

Doidge [18] describes how neural wiring is laid down when we learn a new skill and how repetitive effort stimulates myelination of the neural pathways, which speeds transmission of nerve impulses. If we do something repetitively, the brain assumes it is important and myelinates the neural pathways for that particular activity. Myelination speeds the movement of messages along a neural pathway by providing the mechanism for nerve impulses to leap along the neural pathway rather than simply travel along. Doidge [18] describes how in the same way that a tennis player who practices for hours a day develops lightning fast neural pathways, which create speed and finesse in their responsiveness and movement, a person who ruminates, e.g., on a fear of germs, will build a highly sped-up response to a concern that their hands need washing.

Schwarz took this understanding, that what you focus on grows, i.e., builds myelination, and decided to test a new approach. He taught the detached observer stance of mindfulness meditation, asking his patient to notice the impulse to wash, but instead of acting on it, to reinterpret the distress and remind themselves that their brain circuit is playing up again and then simply shift their attention to something completely different, preferably a pleasant activity, which might trigger dopamine release, an ingredient that supports building new neural pathways. Basically, Schwarz was working to diminish the speed and activity on the orbital frontal cortex – striatum circuit – so that, in the same way as a language that is not practiced is lost through diminished activity on the neural pathways, the activity of obsessive behavior gradually diminishes through the diminished attention it is given.

The example of the neural processes involved in OCD begs the question – Could some of our therapies for depression or trauma, by focusing attention on the source of distress, actually be increasing the distress? Could a similar exercise to that used by Schwarz help a depressed person trapped in negative rumination benefit from noticing the thought and, without further engaging, turning attention away to something engaging and pleasant? They could instead, for example, build new positive connections through, e.g., compassion or self-compassion meditations and/or pursuit of pleasurable activities, e.g., gardening, music, turning attention outward to benefitting others?

Richard Davies' very early experiments with compassion meditation highlighted a practice that fMRI demonstrates, works to change brain function, calming the amygdala and the consequent cascade of chemistry that can lead to depression and instead building the brain activity that increases feelings of well-being [26]. Schwarz used mindfulness meditation to break a hardwired cycle of neural messaging to end

compulsive behavior and enable the building of new automatic reactions, again changing neurophysiology and neurochemistry (Doidge). These are just two evidence-based examples of the types of activities that can work with neuroplasticity. There are many others using not only meditation but a range of activities, which might better suit one or another person's disposition. Suicidology has yet to trial the application of neuroplasticity for its therapeutic benefit in stabilizing depression and suicidality and mitigating the impact of PTSD, e.g., calming the amygdala.

Positive Psychology

Through the partnership between researchers of positive psychology and neuroplasticity, we have also been shown that there is a repertoire of activities people can learn that, if practiced regularly, can change the brain – its structure, functioning, and neurochemistry, to manage and continue to diminish depression, anxiety, and PTSD.

Seligman [54] explains that positive psychology has evolved since its original goal was authentic happiness [53] to having the goal of understanding and enabling *well-being*. Where happiness was inevitably subjective in its measure and could be absent, well-being is a platform from which the vicissitudes of life can be met resiliently, where suffering is not compounded by anguish but approached with greater equanimity and a search for the most constructive response. Positive psychology encourages an internal locus of control, the development of concrete techniques to stabilize and manage navigation through distress or difficulties.

The core features of well-being include positive emotions; engagement, interest; meaning; and purpose. Additional features include self-esteem, optimism, resilience, vitality, self-determination, and positive relationships. Positive psychology has been growing for two decades and provides empirically tested tools for individuals to reflect on and assess their *signature strengths* [53] and has validated a range of techniques to develop the skills and ways of thinking that generate well-being [54]. These tools for reflection and to build strengths enable choices, including building strength in areas where the person is vulnerable and developing grit and/or a number of other resources, which have been shown through controlled trials, including with fMRI, to work with neuroplasticity to decrease distress, depression, anxiety, and address PTSD.

There are 24 signature strengths [identified through the values in action (VIA) test] that fall into six categories:

- Wisdom and knowledge – curiosity, love of learning judgment, ingenuity, social intelligence perspective.
- Courage – valor, perseverance, integrity.
- Humanity and love – kindness, loving.
- Justice – citizenship, fairness, leadership.
- Temperance – self-control, prudence, humility.

- Transcendence – appreciation of beauty, gratitude, hope, spirituality, forgiveness, humor, zest.

Simple techniques have been shown to make a measurable difference to mood, sustained over time. For example, the gratitude visit, where the person reflects on someone still alive in their past who did or said something that changed their life for the better, someone they could meet face to face next week.

The gratitude visit works to build a mentality of gratitude, for the person to eventually begin to notice automatically the positives in their life, rather than focusing on the gaps and on what may or does go wrong.

The aim is to write a 300-word letter of gratitude to this individual and deliver it in person. The letter should be specific about what the person did and how it affected the writer's life. The writer should share what they are doing in their own life now, how they often think of this individual – be generous. Then call the individual and tell them you would like to visit, but do not give away the surprise you have in store for them. During the meeting, the writer should take their time reading out the letter and pay attention to the reactions of the recipient as well as their own reactions.

After reading the pair, discuss the content of the letter and share how they feel toward each other. People who have undertaken this exercise report feeling happier and less depressed and similarly so a month later. These exercises may seem like the sort of thing you might find in a popular magazine. The difference is that all the positive psychology exercises have been empirically tested with large sample sizes and random assignment to treatment and placebo control groups.

Another simple exercise, What Went Well (3 Blessings), is undertaken for 10 min before sleep at night. The aim is to gradually develop a focus on what goes well and to savor it, rather than only be aware of what went wrong in the day or is sad in the world. Initially the person is asked to write three things that went well that day every night for 1 week. It is suggested that sleep quality is also improved by the person having shifted focus to positives before sleep, rather than going to bed ruminating on problems. People have tended to continue this exercise well beyond the trial time, and it becomes a tool they can resume using when they are experiencing adversity for the anchor into warmth and hope it provides. Again, its effect has been measurable and demonstrably transformative.

The exercises developed by positive psychology practitioners have been trialed with a range of populations, including depressed populations, with measurable significant outcomes. For example, moderately depressed young people received a package of six exercises over 6 weeks, resulting in a significant reduction in depression into the nondepressed range compared to the control group, with benefits sustained over a year [54].

This collection of exercises and meditation techniques may provide a range of approaches, from which individuals can choose to best suit their disposition or capacity. The confidence built through successfully self-managing diminishment of depression, having a range of tools to draw upon and the repertoire of skills thus developed and proven effective, provides evidence to support optimism when the person must deal with the impact of future adversity.

Conclusion

The research literature on resilience built over the last 80 years, along with the more recent contributions of positive psychology and studies in neuroplasticity, is much greater than could be fully captured in this one chapter. Rather, this overview has been intended to provide a simple introduction to a rich cache of resources. Much of the literature on resilience is based on robust research undertaken through well-designed studies and, more recently, with the hard evidence of observable changes in brain function through fMRI and changes in neurochemistry, demonstrating the efficacy of a range of techniques and the sustainability of their positive effect. I believe the bodies of research described herein are worthy of further investigation for the contribution they can make to suicide prevention, treatment, and providing the tools enabling self-management of recovery and building resilience.

Abstract

Many studies have explored the factors that placed individuals at risk of suicide. Yet, there is much that can be learnt from the lived experience of those who have been resilient in the face of trauma and those who attempted or planned suicide, who then chose to live and describe their life now as characterized by resilience and well-being. How did they navigate their recovery and prevent relapse? Could their insights and experience suggest transferable skills to benefit those still vulnerable to suicidality?

A. M. Chauvin (✉)
 Menzies Health Institute, Queensland, Australia
 e-mail: a.chauvin@griffith.edu.au

This chapter explores the lived experience of 17 individuals, who shared the path they navigated through recovery to resilience after planned and/or attempted suicide to explore how their experience might benefit those still at risk of suicide.

The elements of resilience, which emerged as pivotal for these people, largely reflected the elements identified in the research literature on resilience, which has been growing since World War II. It was, however, the stages of recovery the 17 participants described and their self-management of recovery and building resilience that offer new insights for suicide prevention, support of recovery and building the resilience, which prevents relapse. Perhaps most importantly, participants echoed to one another in saying that having self-managed recovery and weathered setbacks to successfully reestablish well-being was in itself a great part of what built resilience, *“Having come through this I now know I can get through anything.”*

Introduction

Research and interventions for suicide prevention, have usually been based on what we know about the risk factors leading individuals to attempt or complete a suicide based on retrospective studies of attempted and fatal suicides and significant investment continues to be made in the establishment of suicide registers across the globe [3]. Although this line of questioning has been useful, it has overlooked the valuable information that can be shared by those who have reached the brink of suicide and/or attempted suicide, but have then decided to live and have self-managed their recovery and prevention of relapse.

There is much we can learn from how these people managed their recovery that could inform interventions and support for those still at risk. How did these resilient survivors navigate through one of the darkest and most terrifying moments in life, identify the steps for their recovery, and then construct a path to well-being and resilience?

To begin to understand whether any consistent themes emerge from lived experience, which may indicate transferable skills or strategies for those still vulnerable, a grounded theory research study was undertaken with 17 individuals who came forward after an invitation to participate was circulated through social and professional networks on the Internet.

Grounded theory is predicated on the understanding that, where no research has previously been undertaken, on which to build, it is necessary to use an approach to engagement with the affected population, which allows the space for the consistent themes to emerge, which reflect what interviewees hold most important. This begins to provide the concepts and hypotheses that drive the next layers of enquiry, which could include further interviews, broadening the range of key informants or might indicate research disciplines that need to be investigated. Thus, grounded theory allows the emerging data to drive investigation and development of theory, when no previous research and therefore no theories have existed ([1], 2008 edition).

Grounded theory research begins with open-ended interviews and proceeds through iterative cycles of interrogating indicated research literature for theoretical and technical data gathering, then explores veracity of analyses and interpretations with the original participants and with experts in the field, and then tests the goodness of fit and applicability of findings with the affected populations, clinicians, and other mental health practitioners.

The affected individual, the person with lived experience, is positioned as an expert with knowledge and insights to offer, a collaborator in enquiry and who can contribute to co-design of the application of findings in development or improvement of services and programs.

The lived experience of participants in this study reflected themes that have previously emerged in the large body of research on resilience, which has been growing since World War II, and many of the strategies participants implemented align with the burgeoning body of positive psychology literature (► [Chap. 21, “The Role of Resilience in Suicide Prevention and for Recovery After Suicide Attempt: Learning from 80 Years of Resilience Research”](#)).

Participants also, seemingly intuitively, adopted behaviors and practices that have now been demonstrated to work with neuroplasticity to achieve reductions in depression and the hypervigilance of complex PTSD, and these changes in brain activity, e.g., calming areas associated the fight, flight, and freeze submit response, in turn reduce subsequent cascade of neurochemical and neurophysiological changes, which can underpin depression, anxiety, and other sequelae of trauma [2]. Some of the practices participants had adopted now have strong fMRI and neurochemistry evidence demonstrating an equivalent impact to antidepressants, with a significantly reduced relapse rate [2, 4].

The Decision to Live

To understand the process of resilience, this exploratory study engaged 17 people who had planned and/or attempted suicide, sometimes attempting many times before, to begin to tease out whether resilient survivors of suicidality had commonalities in their recovery and the resilience they built to prevent relapse in the face of future adversity. This chapter does not delve into the detail of how these people came to choose to live, other than where it provides context to explain the process by which they drew on resilience factors for their recovery.

Certainly, these individuals described drawing on similar elements of resilience to those described in many of the studies of resilient individuals over the last eight decades (► [Chap. 21, “The Role of Resilience in Suicide Prevention and for Recovery After Suicide Attempt: Learning from 80 Years of Resilience Research”](#)). One important difference, though, was that where meaning in life is a resilience factor cited in these studies, suicidality often reflected a complete collapse of meaning. Recovery depended on the person becoming comfortable with an absence of meaning and their purpose being the reconstruction of a framework of meaning and ethics to underpin decisions about the way forward. It should be noted, though,

that they did not necessarily begin their recovery with this repertoire of strengths and life skills but consciously set out to understand the areas in which they felt they were ill-equipped and vulnerable and then developed strategies to build these strengths.

All participants described that making the conscious decision, that “*suicide is not an option*,” was a turning point. It was distinct from an absence of action. The clear decision, versus passive inaction, provided an impetus, and they described proactively seeking to learn how to “*make life work*.” Having chosen to live, they explained, they had made a critical decision, from which they were not prepared to withdraw.

This does not mean they stopped feeling suicidal, having suicidal imagery, suffering distress, confusion, and depression. All interviewees reported still feeling vulnerable at the time they had first chosen to live. Many said they felt raw, and some said they continued to feel hopeless at first. Eight people described choosing to live to avoid hurting others and explained that they still had not wanted to live initially, but had chosen to do so to avoid harm to loved ones. Some of these participants described believing they would never experience happiness, but that, having decided to live, they would have to learn how to make their anguish tolerable. Others described reflecting on surviving previous trauma and using this to cultivate optimism that they had the strength to survive the current distress and that in time it would pass too.

The decision to live and find strategies to deal constructively with suffering reflected taking control of the healing process and this internalized locus of control appears to have been key to recovery and building the confidence and self-efficacy, which underpins resilience. All participants described eventually becoming curious about what they could do to heal themselves and to learn to cope with hardship better in the future, rather than hoping to be rescued or have adversities removed.

As participants went on to describe their recovery process, they explained there were a number of decisions they made after having made the decision to live. As elaborated on later in this chapter, some of these decisions marked the ends and/or beginnings of different phases in their recovery, e.g., cocooning to stabilize; completion of grieving a loss; recognized that they have survived trauma before and that they could again; recognition of existing strengths and of the skills and strengths they still needed to learn; and/or reaching a readiness to re-engage with others and the ways in which they felt safe to do so.

Other decisions reflected recognition of boundaries they needed to assert, social circles they wished to enter or reject, and every participant at some point made a decision to shift their focus to what they could contribute to others, with every one of them taking up or recommencing volunteering in some sphere.

In summary, these decisions can be paraphrased as follows:

Initially:

- Suicide is not an option.
- I will learn how to heal myself and make life workable.
- I will learn to live well and to do no harm to myself or others.
- I will never allow myself to be pushed or slide to that edge (suicidality) again.

Eventually, sometime later, when life had recognized and they were confident in their ability to deal with adversities in life, they describe that they decided

- I can go beyond surviving and make decisions that help me flourish.
- I will make choices based on what gives me happiness.

What Resilience Factors Did These Resilient Survivors Draw On?

There were a number of common resilience factors that emerged for participants, which echo what has been described in the resilience research literature (► [Chap. 21, “The Role of Resilience in Suicide Prevention and for Recovery After Suicide Attempt: Learning from 80 Years of Resilience Research”](#)). These resilience factors were adapted and applied differently by them in different contexts and at different times. These resilience factors were

Meaning, which was important for three reasons:

- Suicidality had reflected a collapse of meaning and participants described having to live for a time with no meaning, no anchors, and no reassurances.
- Participants recognized the meaning they attributed to life experiences, especially adversity, could be positive or negative in its impact on them and learnt to reframe trauma as an opportunity for growth.
- As they progressed through recovery, new frameworks of meaning evolved and, with this, so did their identity, perspective on life adversities, and response to adversity.

They were proactive – Participants often used the word “*consciously*” in their sentences and described taking control of recovery and rebuilding – consciously seeking out or constructing strategies to heal, build protective factors, and remove risks from their lives.

Reached out: built connections – They described consciously reaching out and building connections with positive, constructive, supportive people, and often eventually withdrew from those who they felt had a negative impact or increased their risk or vulnerability. Sometimes, they simply sought connection through more anonymous engagement with social, sporting, music-focused, spiritual, or other groups.

Described exercising various domains of intelligence to navigate recovery

- Analytical intelligence – reflection, analysis, problem-solving.
- Emotional intelligence, insight, mindfulness, stress management, empathy, conflict resolution.
- Spiritual intelligence – spiritual and religious frameworks for reflection; creating and using rituals to grieve loss or cleanse after violent abuse; developing boundaries, while remaining compassionate.

Dealing with setbacks and new adversities

- Practiced reality-checking and learnt not to self-punish.
- Became indomitable – “*Just put one foot in front of the other*” and it will get a little bit better each day.

“Decided to become a better person,” consciously reassessed and/or built an ethical framework and committed to align their choices and actions to it.

Choosing happiness – Decided that “*happiness doesn’t just happen – you have to build it*”, “*Find what you love doing . . . and do it*”, “*What passion would make you jump out of bed in the morning?*”

The Process of Recovery

Many participants explained that it was the process itself of self-managing recovery and rebuilding that was the primary factor in their growing confidence in their ability to cope. The process by which they determined each new strategy during each stage and as they moved from one stage to the next reflected the development of a habit of pausing to observe and reflect, then analyze and problem-solve; to decide on what next step they needed and felt ready to take; and to consider the resources, life skills, or support they might need to implement that next step.

All participants described their capacity to reflect and problem-solve as one of their strengths, describing it variously as mindfulness, observation, and curiosity, and they were proactive in reflecting, searching, and researching in response to new questions or challenges arising in the recovery process or new adversities arising in their life, drawing on support, skills building, and other resources as needed.

They set small achievable goals, and with each success, they explain that they grew more confident in their ability to deal with “*whatever life might throw at them.*” This process enabled them to consciously draw on the range of resilience factors, when and as they needed them.

This growing body of evidenced successes in the face of adversity built their confidence and optimism, which in turn laid the foundation of resilience to future adversity.

The process of moving forward through recovery from suicidality was not always linear, with setbacks and new adversities causing them to pause and stabilize once more, while they considered what they could learn from their latest challenge, to build strengths and reduce risk in the future.

Whether the distress arose from experiencing a setback when a strategy failed or because a new adversity had arisen – with each setback or new adversity, the same

pattern was retraced – pausing and stabilizing; seeking connection, comfort, sound-ing boards; then proactively considering the next steps to resume or continue recovering and rebuilding. As time passed and their confidence, skills, and support systems consolidated, participants explained they began to focus on moving beyond survival, toward flourishing.

Cultivating a skill of observing themselves also helped them recognize early warning signs that they needed to take stock or to take time out to stabilize themselves in the face of a setback. In each instance, the cycle of reflection, analysis, and choosing actions continued to form the process for developing strategies to heal wounds and build a constructive approach to daily life.

Participants became more reflective and proactive in their choices, more consciously working to prevent avoidable trauma and provide reliably constructive responses in times of distress. *“I now react with curiosity – what is it that is going on here? What can I learn? What can I do differently next time?”* (interviewee 10).

By observing the consequences of their choices, both in their effect intrapersonally and in their interpersonal and broader life context, their insight grew, *“I realised my rage at the abuse I had suffered was consuming me and so I decided to find a strategy to see things differently –to understand the cause of my husband’s behaviour – to be able to forgive. I had to look at my role in it – I didn’t go to the police”* (interviewee 6).

Their growing skill and insight enabled them to either build on the most recent positive step they had taken or to rethink and try something else. Interviewee 6 realized she needed to use a multilayered approach to be able to let go, *“to stop flooding in anger/rage”* and move on with life, so she took up yoga, meditation, and Reiki. She reflected on what helped soothe her and so spent time at the ocean. She describes that when she had experienced stability for some time, she got on with building a new life, getting a job, coming out as gay, and building a profession in the social welfare and advocacy sector.

Participants describe that over time adopting an approach of pausing to reflect, analyze, and problem-solve appears to have resulted in them developing a new automatic reaction to adversity, that is, to respond with curiosity, seek to understand the new challenge, and reflect on how it might best be addressed. Pausing and reflecting on the emergence of each new challenge before taking action, rather than acting impulsively, angrily or otherwise in emotional, verbal, or behavioral reactions that might exacerbate the situation, became an essential element of their growing repertoire of constructive responses to adversity.

Participants explained that it was the process itself, of self-managing recovery and rebuilding, which was a primary factor in their growing confidence in their ability to cope with the present and future challenges.

Phases of Recovery

During their self-managed recovery, all participants described traversing three clear stages, including (1) stabilization; (2) recovery and rebuilding; and (3) flourishing –

building happiness. In some ways, these stages formed a continuum along which they moved, with gradual transitions from one to the next.

The first phase was stabilization, which was characterized by withdrawal, finding anchors, and then, eventually, reconnecting safely with daily life. Following stabilization, participants worked actively at recovery and rebuilding. Recovery and rebuilding often fed into each other – resilience was dynamic and always evolving. Recovery sometimes included consciously designing a healing process, which could range from an exercise regime through to esoteric practices.

Rebuilding their life was most often pursued by proactively learning the life skills they felt they lacked, strategies for self-care, and ways of opening up new opportunities. The final phase was building happiness and strategies to enable flourishing. In this phase, participants deliberately chose positive pathways forward, making choices based on a belief that they were responsible for their own happiness and that happiness can be built. They filtered these decisions through the moral compass and the capacity to live consciously, which they had been developing during the recovery and rebuilding phase. Sometimes, they moved back and forth between the phases of recovery, especially if they suffered setbacks or new challenges. Elements of resilience were always drawn on as needed at different times through the reflective process that they had learned.

We examine these phases a little more closely.

Stabilization

Many of the participants in this study described experiencing a complete collapse or loss of meaning at the time of their planned and/or attempted suicide and for a period thereafter. They described feeling raw, unable to think, and feeling acute distress. They described seeking strategies to calm down and stabilize. Some needed solitude, others company. Where they sought company, however, 10 participants described that they did not want to discuss their trauma. Instead, they just needed warmth, comfort, or simple distraction through shared activity.

Cocooning

A number of participants described that immediately after deciding to live they could not think clearly and that they intuitively or instinctively recognized a need to withdraw and cocoon themselves for a period, to stabilize before they could commence their recovery. Initially, their withdrawal often reflected mental exhaustion and simply wanting to be in a safe space to calm down. Interviewee 3 referred to his initial withdrawal, during acute distress, exhaustion, when terrified and unable to think, as “*Doona Therapy, you know when you climb under the doona (duvet) and stay there for two weeks*” (I 3). He chose to do this as a self-admitted patient in a psychiatric clinic, where he explains he was grateful the psychiatrist in charge allowed him his complete withdrawal and let him choose when and how to re-engage.

Keeping it Simple and Having Some Structure

Many participants described how it could take months of just pacing through each day, perhaps attending a gym or spending calming time around strangers in a public place or with friends, before they felt their strengths had consolidated and they had enough confidence in their stability to try new settings or activities. Participants also described how important structured daily activities and/or routines were, “*Structure was what got me through the day*” (I 2), particularly on days when they were distressed, when their mind was foggy or unable to think clearly, and they needed a way to pace through their time of stabilization. Structure and engagement in activities, “*Do something, anything*” (I 3), provided a safe arena as participants identified and began to apply their strengths in the course of navigating simple daily activities.

Knowing When to Re-Engage

Sometimes, it took much longer before the person was ready to come out of their safe cocoon, e.g., when grieving a loss, recovering from extreme, and prolonged abuse. Sometimes, participants set a time frame for themselves, such as interviewee 2, designing and undertaking a 1-year Wiccan healing ritual. Other participants described simply waking up one morning and finding they were feeling ready to get on with moving forward, e.g., when the turf was laid next to the newly completed stone wall, which they had built with their own hands (P 2). Some described simply waking up with an idea to start something new, like joining a musical group (I 10), taking up volunteering, or feeling ready to call friends or family for the first time after a long disconnection (five participants).

Participants described how, as the years went by, they would sometimes repeat such periods of withdrawal when setbacks occurred or when they found themselves in acute distress, until, each time, they felt ready to begin engaging and moving forward once more.

Beginning the Proactive Steps of Recovery

Finding Anchors to Strength

During times of withdrawal, and as participants began to be able to think more clearly, they describe how they began reflecting on the strategies that had worked for them in the past when faced with trauma and distress. They described how they chose to recommence doing some of those things, such as ensuring they had adequate sleep, eating well, choosing positive social connections, going to the gym, and using art and music to process or express emerging feelings.

Participants described how they reminded themselves of their strengths and the approach or activities they had used previously to successfully overcome adversities (six participants). Identifying what had previously worked also reminded participants that they had survived hardship before and generated the realization that they were not a weak person but in fact someone strong, who had survived before and could again; and that bad times had passed before and would again. This realization

provided a reassuring anchor at times when they found themselves buffeted by strong emotions or difficult situations, and it helped them to begin generating some hope and optimism about the future (six participants).

The realization that they had survived past trauma, tragedy, or hardship in the past and experiencing success when responding to challenges in the present were both pivotal to believing they could also recover from the trauma of suicidality. *"A history of competence and successful effort . . . builds confidence – to try different things, not just do as you are told"* (I 13).

As they described their progress through stabilization, it became evident that with each successful implementation of a recovery strategy their confidence grew and they were more inclined to stretch further next time. For example, interviewee 1 began by volunteering in a thrift shop and then eventually moved on to volunteering to tutor a refugee family in English language; interviewee 10 progressed from a long period of finding anonymous company in public spaces to meeting with other musicians to play music together.

Reaching Out: Building Connection

Eleven participants described that during stabilization, when they did not need solitude, they just wanted to feel comforted, warmly affirmed, share in distracting activities, share positive experiences, do pleasant things with another person, or be amongst kindred spirits, and kind people. For some participants, the need to feel connected to humanity returned while they still felt unprepared to expose themselves emotionally, describing themselves as feeling too raw (I 9).

Interviewee 10 had found that at his most fragile he could not bear the company of "negative" individuals and was finding his social circle to be so. However, he found being alone left him too much time to ruminate – *"thoughts are your own worst enemy"* (I 10). He describes how he first tried to solve the need for company, to feel connection, by going to the local hotel and sitting at the gaming machines, but, despite being surrounded by people, this setting exacerbated his depression.

He describes that he then solved the problem by going to sit at a local seawall each day, pretending to read a book, so he could be around people. He gradually began to recognize other regulars, who, like him, did not wish to engage in conversation but were happy to nod in greeting, and he described enjoying a sense of community. Eventually he felt ready for closer relationships but explained that he was still not ready to talk, for fear of being asked about issues that, he said, were still too raw. Instead, he used his musicianship as a vehicle to connect and joined a group of other musicians to play together each week. This shared experience provided the level of intimacy he needed, without risk of overexposure. Interviewee 10 had been very clear about the connection he needed and had developed ways to meet that need at the various levels of comfort he was capable of at different times as he recovered.

Other participants variously went to the gym, bushwalking club, belly dancing, yoga, enrolled in classes, volunteered in youth services, joined cycling groups, and when they were wanting company but did not want to have to engage in exposing conversations.

Reaching Out for Support

Participants did reach out for help from time to time, but, in reviewing the interview records, it became clear that these individuals were preferring to self-manage their recovery from the trauma of suicidality, and when they reached out to a health professional, pastor, or some other support, it was as a sounding board or resource to help them in their reflection, analysis, and development of strategies and decisions for moving forward. *“It’s important to learn what options are available, ‘I didn’t know options – I should have sought help – there are now so many choices’”* (I 3). They were clear, however, especially when in their acute distress immediately after choosing to live and while stabilizing that they did not wish to *“be forced”* to discuss the traumas that had led them to be suicidal.

The experts to whom they turned at different times included

- Themselves – looking back on how they survived trauma in the past, what worked, what did not work, affirming their own strengths.
- Role models – consciously looking at people they respected, who appeared to be good at surviving and studying those people’s qualities and behaviors. This could be a distant figure – a Nelson Mandela-type of person, or someone in their own sphere of existence, a friend or relative who they admired and respected.
- Spiritual guides – drawn from the range of religions, from traditional Judeo-Christian, Islamic, Buddhist, through to Wicca and to humanist philosophers.
- Health professionals and counselors of varying disciplines, skills, and qualifications.

When participants described seeking out health professionals in the early stages of their recovery, it was sometimes for crisis intervention, e.g., calling Lifeline, a crisis telephone service. All participants confirmed they had reached out at some points during recovery from suicidality. Who they considered to be helpful varied and may have depended on the skill of the person to whom they turned.

Some sought out psychiatrists (three participants); psychologists (three participants); Lifeline (one participant); the family doctor (two participants); marriage counselor (one participant); religious leaders/pastoral care (one participant); yoga (two participants); other spiritual groups (including Christian, Buddhist, Theosophy, Wicca, Spiritualist, Reiki) (five participants); returning to indigenous culture (one participant); Internet chat room (one participant); and lawyer (one participant).

Of the three participants who sought out the family doctor, two described the experience as disappointing as the doctor reverted immediately to medicating with antidepressants, when what they had sought was a sounding board with whom to discuss their experience. Their doctors offered no opportunity to talk through issues and no referral. Of the three psychiatrists, one also focused solely on medication; one provided psychotherapy; the other was described as very receptive and respectful, allowing the participant to withdraw and come forward as they needed (I 3). When interviewee 3 was ready to talk, his psychiatrist provided both one-to-one and group engagement, resulting in 6 weeks of therapy and then a weaning onto

self-management through an outpatient relationship, at which point he decided to move interstate to “start over.”

If the relationship with a health professional was perceived as respectful and the participant gained the support and insight they required to build some new skill or navigate a difficult situation, they returned to that person at other times when necessary. Where the health professional imposed control and was not responsive and particularly when the health professional simply medicated and did not support reflection and problem-solving, the participants not only ceased to engage with that person, but sometimes developed great resistance to seeking out a new health professional in the future. Exposure to what was perceived as poor practice became a barrier to any further help-seeking.

Moving from Stabilization into Rebuilding

The Awakening of Curiosity and Determination: Becoming Proactive

Not all participants were resilient people at the outset or, if they normally had been able to rebound from adversity in the past, for a number of multiple traumatic circumstances had arrived in a sequence, which left them feeling battered, exhausted, and having lost confidence and hope, resulting in them planning to suicide and/or their attempted suicide.

As they stabilized, all participants gradually became curious about how they could have fallen into such hopelessness that they had planned or attempted suicide and they determined they needed to understand how to prevent “*ever going back there.*” They reflected on their acute distress and what insights, skills, or qualities they might need to develop to prevent any such future decline. When they felt ready, participants actively pursued growth in the areas they had identified, first to simply recover and rebuild and then, eventually, to flourish. These, as outlined previously, might include stress management (yoga, meditation, being by the ocean, music); conflict resolution; self-care, e.g., early recognition of warning signs of decline/“burnout”; and techniques to stabilize and reconfigure commitments; improved boundaries; and other life skills.

Participants had identified life changes or new skills, which they needed. As they gained these and they became more firmly established, they then made decisions to pursue strategies that would improve their future life options. Also, 15 of the 17 participants pursued professional or other qualifications or starting a new trade/business. These strategies were based on reflection on their circumstances, analysis of their personal and other resources, and then structuring a path forward to achieve their goals.

Participants considered their next course of action a step at a time, i.e., gradually, building skills, positive connections, and opening up options that took them further from the risks that had led to their suicidality, all the while building their confidence in their ability to solve problems and overcome future adversity. For example, I 3 moving from private enterprise into volunteering for community-based services and then becoming qualified in an allied health profession; I 12 ceasing drug use and sex work, then becoming a hostel volunteer, then undertaking a social work degree

and now successful as a welfare professional. Interviewee 7, finding her first employment after escaping abuse, worked in aged respite care, and then, feeling more confident, enrolled in a course to regain her nursing qualifications, then again, having regained confidence in her academic capacity undertook a degree in nursing and eventually, over time, became a specialist in stem cell treatment.

If the strategy they initiated proved useful, they took time consolidating that strategy until they were ready for a next step or until a new hurdle arose. If a new strategy proved unhelpful, participants returned to reflecting and thinking of improved or alternate courses of action.

All participants described how they moved through the regular cycles of observation, reflection, analysis, and problem-solving, making a decision on an action, and then taking that action, to design a response to whatever new challenge or question had arisen.

This did not mean they were immune to despair or to self-flagellation at setbacks but they were developing an ability to move through these negative emotions more swiftly by developing a habit of reverting to the self-care, stabilization, and reflective problem-solving more quickly each time. This served to focus them constructively and cut short self-destructive patterns of thinking.

Their first cycles of reflection, problem-solving, and trying out strategies had been focused on stabilization, finding anchors, and building confidence. Embarking on cycles of reflection as they began to rebuild their life had sometimes been undertaken in a state of great anxiety, fearful that they would discover there was no hope, that they were flawed and would never learn to manage life or that life's challenges. They described saying to themselves at these times, "*One step after another*" (I 15), and determinedly reframing setbacks or failed strategies as opportunities to learn.

They Exercised Some Domain/s of Intelligence

Participants came from a range of backgrounds and education levels varied; nevertheless, their reflection, analysis, and problem-solving reflected the application of analytical intelligence and life skills. Their decisions over time about how to handle interpersonal problems, which friendships to cultivate, and the decisions they made to move away from destructive social circles, all demonstrated increasing emotional and social intelligence. They considered spiritual practices that might help with recovery from loss or abuse. Where they did not find a fit with existing groups and/or belief systems, some conceived helpful rituals, which they carried out. These might include cleansing meditations and rituals after abuse, memorial and farewell rituals after loss, self-care/compassion rituals, etc. Some actually referred to this as spiritual intelligence.

Analytical Intelligence

The cycles of reflection and action, which participants used, demonstrated their application of analytical intelligence. Their analysis did not necessarily require

sophisticated intellectual skills. It was more often simple, pragmatic reflection, information-gathering, and problem-solving, such as when interviewee 10 had solved the dilemma of needing human connection but not wanting to share his distressing thoughts and had sought out social settings, which would provide him with the company he needed, without risk of intrusive and unsettling conversation. Interviewee 5 had used a time of convalescence from a workplace injury to come to grips with seroconversion to HIV and to commence study to open up future employment options.

Interviewee 12, similarly, opened up new options by methodically constructing a path away from sex work and substance use, building skills and confidence through volunteering, and then studying for a degree in social work. Interviewee 6 reviewed the options open to her and created a business, which would give her financial independence and freedom to choose to leave her abusive husband. Interviewee 7 sought legal advice and began systematically secreting away some housekeeping money each week until she could afford to leave her abusive husband and rent a house. She then had undertaken the respite work, which built her confidence, leading her to then undertake refresher training as a nurse and re-entering the workforce, eventually becoming a well-regarded specialist in her field. Each person had eventually methodically undertaken strategies to build a secure future away from the risks, which had undermined them in the past.

Participants used the word “*consciously*” frequently when describing the steps they negotiated, and they described how each step gave them a renewed sense of being in control of their future, i.e., they were consciously, systematically constructing a course to a positive outcome, not waiting to see what the abuser or “fate” would hand out. *“Think about what good things you want and ‘set those as a goal; break it into tiny steps; take tiny steps each day – with measurable outcomes’”* (I 4).

Emotional Intelligence

Participants demonstrated emotional intelligence in their recognition of needs for self-care, kindness to others, and constructive approaches to difficult interpersonal situations.

Building Positive Connections

All participants had reached a point where they were ready to reach out and engage with the world again and to eventually, “*consciously*,” build positive, supportive connections. The level of connection they sought varied as they progressed through stabilization, to being more actively engaged in the world again. The reflection on their capacity and pacing themselves through nonchallenging warm or even anonymous company, through to more intimate or exposing engagement, reflected growing insight.

Some described finding positive company by joining church groups (I15); attending Salvation Army services “*found the Salvation Army listed in the phone book of*

the hotel . . . felt love and caring . . . they gave me the stamina to return to the Community Health Service where I was working" (I 9); joining Wiccan groups (I 2 and I 8); attending belly dance classes (I 6); going to the gym (I 1); taking up cycling (I 14); running (I 12); and bushwalking (I 2; I 13).

Self-Care

In becoming curious about how they fell into such hopelessness and determining that they would learn to recognize risk and develop a repertoire of strategies for survival, they exercised kindness toward themselves and described "*case managing myself*" (I 12) and becoming "*my own therapist*" (I 1; I 12; I 13). The act of trial and error and sometimes achieving even small goals was described as what gradually built their confidence in their ability to face future adversity and find solutions to problems.

Participants described how it could take months before they felt their strengths had consolidated and they had enough confidence in their stability to try new settings or activities. Sometimes, it took much longer if the trauma or loss was significant or if recovering from extreme, prolonged abuse. What stood out was how well participants had learnt to recognize when they were in a vulnerable state and their limitations.

Perhaps even more important, though, was the positive impact of learning to deal with a setback when a strategy did fail. Four participants described responding to a seeming failure or new adversity with "curiosity" and compassion rather than a self-punishing approach to reflection and analysis. Their reflection and problem-solving were solution-focused (I 11) rather than self-flagellating or a descent into hopelessness or self-hate (P 1; I 1; I 2). It was particularly in relation to setbacks that participants described "*being their own parent or best friend*," using self-soothing and self-talking to resist the slide into depression, fear, or hopelessness (P 1; I 1; I 12).

Participants demonstrated self-discipline, although it was not always conscious, in continuing to "*get back up and have another try*"; describing how they attempted to learn from failure and to construct a new strategy to keep consolidating strength and improving life, "*the thing with life is not to move through gracefully but to slog on regardless*" (I 1).

The self-care intrinsic to charting a course of recovery was in itself a protective factor as participants explained their increased mindfulness built their capacity to recognize warning signs of vulnerability early (P 1; I 10) and how to pace themselves at these times. Four participants described learning to recognize signs of duress or decline and recalibrate their lifestyle to reduce risks, stabilize again, and determine their next steps. These participants described eventually learning to take an approach of kindness and curiosity in their cycles of reflection and problem-solving and in their decisions on each next strategy.

Eight participants evidenced this same kindness and curiosity in the language they used when describing how they dealt with setbacks, how they "*reality-checked*," how they have all learnt to see the failure of a strategy, as an opportunity to learn, rather than falling into self-recrimination and hopelessness.

Insight Applied to Developing Resilience

Participants described gaining insight into their triggers for depression and beginning to understand the negative or positive impacts of their social connections. Many described realizing that they would need to leave behind the friendships, which impacted negatively on them and would need to build new social networks. Interviewee 5 described realizing that he had grown up in a social context that normalized drunkenness and violence and in which there had been no role models for how to engage constructively with others for fruitful and intimate relating. He responded to this insight about his past by choosing to engage in a remaking of himself, *"I am having a makeover."*

He reflected on his chronic illness and decided he could try to be a role model, public speaker, and support to others with the same condition, and he drew on support organizations and services available to him to learn the skills he would need to do so.

Interviewee 3 described how his identity had been bound up with his image as *"the man who has it all,"* who was successful in business, wealthy, in a beautiful home, happily married. When his life unraveled financially and his wife abandoned him, and after his aborted attempt at homicide/suicide, he decided to take stock and commence a new life in a new place, based on newly identified values. He became a volunteer caring for people with terminal illness and then eventually found employment in health and welfare services, rather than resuming private enterprise. He described how he now takes pleasure in quality relationships and is *"happy with my lot . . ."* He has not regained the financial wealth he lost, nor his previous status and image in the community, but he now values quality relationships and being a contributing citizen above these. He is choosing to make the best of a very different socioeconomic status and finding he prefers his new social milieu.

All participants described reflection and problem-solving as critical to their recovery, and when asked what their emotional strengths in response to adversity are, they explained, *"Being able to pause and reflect, rather than react impulsively, . . . problem solving."* Some decided to take on the formal practice of reflection and development of insight through mindfulness (originally a Buddhist practice, now adopted by secular society and used by a growing number of clinicians) and other meditation practices to begin to live with greater emotional intelligence and respond to others constructively; notice when the warning signs of depression or burnout arose and recalibrate their lifestyle to remedy their mental state early; and prevent themselves from ever declining to suicidality again.

They all described recognizing they had various life skill deficits and all had, in one way or another, consciously explored avenues to develop the skills they believed were needed to improve their response to life's daily challenges, such as stress management and conflict resolution.

Spiritual Intelligence

Participants sometimes turned to spiritual beliefs and practices, particularly to manage loss and grief but also to move on from abuse, e.g., cultivating empathy

and compassion to reach forgiveness; at other times, creating rituals for grieving, cleansing, or other points of change or closure.

Interviewee 2 explained how she used spiritual practices of Wicca to construct a healing ritual to cleanse herself of the impact of abuse. Pilot 2 described using her withdrawal from the world after her sister's death as a time of solitude to construct memorials, such as a rock wall, to honor her sister. She explained how engaging in physical labor helped her to constructively manage her grief. Interviewee 1 used music to self-soothe and, when he felt ready to see reminders of his mother, such as photos, her possessions, he used these as symbols to work through his grief until he felt he had honored her adequately to feel freed to re-engage with the world and move on.

Interviewee 8 had experienced great suffering from early childhood, with congenital illness causing many hospitalizations, which left him with a pervasive sense of difference, leading to isolation and poor academic performance in school. He describes how he felt highly sensitized to his environment, and he interpreted this as indicative of having psychic ability, which then made his otherness feel like a strength. He described how despite his early efforts as a child to locate and anchor into some spiritual sanctuary he fell into deep clinical depression, which lasted from Grade 4, throughout his school years until 19 years of age. During this time, he also began self-harming, through Grades 6 and 7, *"using cutting as a release."* His academic performance fell, and he began to seek solace in black magic at the age of 14, hoping to learn to manage the forces that he felt plagued him. His thoughts did turn to suicide, and he engaged in repetitive self-harming until he was 18 but he *"had a sense I would not be allowed to do it – that there was some purpose I had to fulfil."*

Interviewee 8 also described how one night he had a numinous experience. He was lying in his bed with an injury and was weeping at the pain, when a column of brilliant light appeared in the center of the room. *"It felt like a positive intervention, God-force"* and from that night *"the lights started to turn back on"* and his depression diminished. He abandoned black magic practices and moved across to the Wiccan tradition of benevolent pagan practices. Although the depression continued to plague him for 8–9 months of the year, the rest of the time he *"felt lighter, fresher – felt the presence of a white light."* He felt it was a spiritual intervention, that he was not alone, and that he was being watched over and needed to live for some, as yet unknown, purpose.

All participants described cultivating new ways of thinking, becoming more insightful and cultivating behaviors and practices, which they found to be a source of spiritual strength. They described working to learn to trust themselves again and described an almost ineffable *"connection with my own spirit"* – gaining an appreciation of their own good qualities, ethics, recognition, and acceptance of their limitations – self-acceptance.

In summary, the participants described a range of spiritual techniques they developed to manage distress, including

- Intuition – when analysis failed, trusting gut feeling (seemingly a mélange of experience, insight, perception of the unspoken exchanges with others).

- Ethical parameters to filter choices, include/exclude possibilities.
- Conscious construction and use of rituals.
- Usefulness of symbols as positive memory cues, e.g., songs, pictures, jewelry, rituals.
- Participation in spiritual practices alone or as part of a group or church congregation.
- Nearly all participants engaged in some form of formal or self-designed meditation and/or visualizations.

Moving Through Rebuilding and Consolidating Strength

The decision to seek to understand what had led to suicidality, to understand their strengths and vulnerabilities and the decision to proactively, one step at a time, devise strategies to build strength and reduce risk were the processes of a resilient person. As participants became more confident in their insight and life skills, they describe they more automatically responded to identifying life skill deficits by determinedly setting out to learn how to develop strengths in these areas.

Participants described that in times of self-doubt they again reminded themselves of their existing strengths using these both as an anchor and as a reassurance to which to return if a foray into building some new strength or life skill did not succeed. During setbacks or if a strategy failed, they explained they might also sometimes return to cocooning themselves, pacing their way through each day, reflecting all the while on what had not worked and they therefore still needed to learn or what activity might be beneficial. As their life skills and confidence consolidated, they described that they also began to visualize or imagine possible positive futures that went beyond just survival to opening up new life options.

As participants became more and more confident and took more risks, trying out new skills, and venturing into new environments, they paced themselves through the anxiety, which accompanied trying new life strategies. The self-talk came more easily: “*I have survived before, I will do it again*” (I 1; I 15); “*I am resourceful, ... always find solutions*” (I 9).

When they could not see through a new adversity or felt they could not think clearly, they had learnt to be patient and simply put one foot in front of the other, resting on structure and routine and reverting to self-care – eat well, sleep, go to the gym, seek distracting positive company. They developed a repertoire of techniques and resources, e.g., putting post-a-note reminders of previous insights on the walls; using books, photos, and resources they had collected to refocus on the beauty in the world, nurturing themselves until they were ready to emerge and develop and embark on their next strategy, something that was happening much more rapidly each time.

It was clear from the participants’ stories that they did not wait for people to come and rescue them, although they did reach out for comfort or a sounding board if they needed it.

They all described that they learnt to reject self-hate and self-punishment when a strategy failed, saying they began to recognize these as tiring and counterproductive. When they were too raw to think, if some new loss seemed too great, they withdrew into self-care and into constructive or distracting activity, such as exercise, gardening, walking the dog, art, music, movies, or whatever they found comforting.

Participants were proactive in their search for ways to heal themselves and became more resilient as they dealt with setbacks and each new hardship. If the attempt had failed, they described trying to not get stuck in disappointment or fall into hopelessness, often using “self-talk” to remind themselves, “*Setbacks happen don’t beat yourself up – just learn from it*” (I 10). They reflected on what went wrong, what they could learn from the situation, and tried a new strategy. While they sometimes slipped into despair, feeling overwhelmed or disheartened, participants described that they had learnt to reach out for comfort and sometimes reached out for professional support.

Becoming Engaged: Developing Altruism Through Volunteerism

Moving through rebuilding and consolidating strength was also a time where many participants turned their focus outward to altruism, e.g., learning skills to become volunteers. For some, it began with a decision to turn their focus outward, to begin to notice others and not be paralyzed in cycles of rumination, self-flagellation, and despair.

By the time I interviewed the participants in this study, they had all, without exception, been engaged in volunteering and at least a third had moved into careers in health, welfare, social support, “*to give something back . . . to help others who might be feeling as vulnerable as I did*” (I 3). “*Random acts of kindness*” (I 6); *being kind “in their own backyard”* (I 4). “*I have always volunteered and found it gives me great pleasure*” (I 6). Whilst some of the participants provided respite care in a range of health and welfare sectors, others became involved in youth programs through community-based organizations. Others took Lifeline Counselling Courses and became a telephone counselor, and some took up volunteering with Red Cross and/or church-associated caring activities.

The sentiment of interviewees 3 and 5 was echoed in some way by almost all participants, “*Take opportunities to smile, make others feel warm*” (I 3). Some, who began volunteering early in their recovery described deciding that if there was no hope for happiness in their own life, then they wanted to try and make a difference to others who might be suffering, e.g., through volunteering – “*Life is hard – I want to do something to ease the suffering of others*” (I 1; I 11; I 13). They describe discovering that they felt more positive themselves when they shifted their focus to others and that the positive effect they felt also provided motivation to keep going.

Interviewee 13 had experienced ongoing major challenges in her life. She had been sexually abused by her step-father, and when her mother did not believe her, she, over time, engaged in multiple suicide attempts. As an adult, her challenges continued, with development of a chronic disease and with her children on the

autistic/Asperger's spectrum. Interviewee 13 decided that she would use what she had learnt through her experiences to help others going through similar traumas, "*I turned adversity into something helpful to others*" (I 13). She became a volunteer advocate and public speaker for mental health issues; worked with a general practitioners' group as a mental health representative; became involved in an organization for young people at risk; and pursued innovative strategies for working with children with autism and Asperger's syndrome.

Without exception, every person interviewed for this study had taken up volunteering and many eventually moved across or retrained to some kind of social service, caring or welfare occupation or profession.

Decided to Become a Better Person

For a range of reasons, participants reflected on the values and ethics by which they had lived, and in all cases, in the course of reflecting on their past and what had led them to suicidality, participants decided that there were some things about themselves that they did not like. For some, there was deep embarrassment when reflecting on their negative or aggressive behaviors, and in response, for some, there was a tendency to self-hating rumination, even though they recognized the latter was not only unhelpful but risked placing a burden on those whom they felt they had wronged, to not only forgive their bad behavior but to cheer them up and reassure them, when the person they had harmed may have needed to be comforted themselves.

A number of participants decided to adopt practices to make themselves a stronger, more authentic, kinder, and trustworthy person, i.e., to do no harm. This was sometimes the motivation for those who had adopted practices, such as mindfulness, meditation, and yoga. Some learnt techniques to calm impulsivity and so felt less of a burden on others and had fewer opportunities to slip into self-hating. Some decided to completely reinvent themselves, such as when interviewee 5 decided he was "*having a complete makeover*," using the opportunity of his crisis to reflect on how he wanted to live differently from his family, who had normalized alcohol and violence in social interactions. He had decided to find other examples, role models, for how to socialize, and how to problem-solve and resolve conflict. In becoming a public speaker about the chronic illness he suffered, he described that he sought to create an identity and lifestyle he could feel proud of.

Interviewee 15 described that he decided to take the complete demolition and rebuilding of himself as an opportunity to find his "*true calling*." He had been arrested by police because they had assumed it was he that was the violent aggressor in a domestic violence alert, not recognizing that it was, in fact, his wife who was the aggressor. He explained he had felt so ashamed that this had prompted his suicide attempt. His suicide attempt had resulted in multiple organ damage, which resulted in 6 months of grueling rehabilitation. His children had responded with anger, making it very clear to him that he "had no right" to tear their lives apart with suicide, and as a result he determinedly worked through a difficult recovery.

Rebuilding his relationship with his children and dealing with their anger and loss of confidence in him led him to decide to identify the ethics against which he could measure himself, so he would always have an honest view of his good qualities and the personal limitations with which he needed to work and be less vulnerable to being eroded by others. He described seeking out a range of spiritual groups, including 12 step-type groups, Christian groups, Jungian groups, and also sought out therapists as resources at different stages, e.g., *"Its important to have a guide to be leading the rebuilding process."* He identified strongly with Joseph Campbell's *Heroes Journey*, the Jungian text on facing and overcoming one's shadow – finding strength in *"choosing a life of spirit and heart."*

Opening Up New Options: Moving Toward Flourishing

As people moved through months and years of recovery and rebuilding, using reflection and problem-solving to assess their needs and resources and choose their next steps, they learnt to scan for options and described that it became clearer to them that they had always had a choice of how to respond to a situation and develop constructive strategies to move forward.

At first, the recognition of the freedom to choose was applied to making more considered and less reactive decisions for survival (I 10). Then, the freedom to choose was applied to considering and choosing ways to reduce risk of decline or relapse, such as moving away from destructive social circles (I 10; I 12). Then, reflection on just what range of choices is possible led to identifying options that would optimize the possibility of positive outcomes in life, *"Be curious about what tomorrow might bring"* (I 5).

Interviewee 13 described a moment where she thought it would be easier to just let go and *"have a breakdown and get admitted and be cared for."* Then, she said that she could not but help reflect on the impact this would have on her children and the thought of her children being left with their father was intolerable, *"Then I realised the choice! . . . and I chose to reframe, relook and begin problem-solving."*

Interviewee 12 began her journey from suicidality after a near-death experience at the hands of a violent partner. She took out a domestic violence order, found community housing, and ceased to work in the sex industry. She took up yoga and explored a range of other self-care techniques and *"worked on building self-awareness."* She began volunteering at a hostel. She described that she liked people, *"I love communication . . . and creating a safe and secure environment for other people."* She discovered she was a gifted case worker, and she described using what she was learning to systematically build her capacity to care for herself. When she felt she had stabilized and was ready to move forward, she enrolled in university and studied social work. She described how commencing studies took her *"beyond survival."*

Participants had many similar stories about methodically reviewing their life, values, and choices. They became clear on the values by which they believed they could make the best decisions for themselves and for their impact on others. Application of the resilience factors to recover had allowed them to see choices

and to apply their moral compass and other criteria to make good choices instead of simply reacting. The optimism generated by experiencing positive outcomes encouraged some participants to decide on complete changes to life trajectory.

All participants actively pursued a range of courses, including self-development, education to pursue “their passions,” took time to be creative, philosophical, and to simply learn new things. Of the 17 people interviewed, 6 described enrolling in or returning to university to develop or consolidate careers.

Managing Setbacks: Reality-Checking

Perhaps the insight to check expectations of life and of others in one’s life is another element of emotional intelligence; however, for all of the interviewees, the capacity to reality-check and acknowledge “*set backs happen – don’t self punish, just solve*” proved to be a critical insight and a skill to prevent relapse into hopelessness. When strategies failed or new adversities arose, some participants slid back toward hopelessness but all described how they then eventually took stock and chose to reflect on what they could learn about the triggers for the setback to reduce risk in the future. They also reminded themselves of what had been working well and what had brought joy in the past and, once again, set about to create those activities, to seek out positive connections.

That is, the same cycle was repeated, i.e., taking time to observe, reflect, analyze, and problem-solve, decide on an action, and then take that action. All participants described ways in which they were “*learning to be gentle with myself, self-caring,*” while still moving forward. When participants suggested practicing greater kindness to themselves, this did not equate to wallowing. Rather, it reflected them responding constructively, seeking to learn instead of sliding to self-recrimination, seeing themselves as a failure. It also reflected them recognizing warning signs of stress or duress earlier and adopting techniques to reduce workload, manage stress, care for their health, and find the positive company they may need while they recalibrate, rather than burn out.

Became Indomitable

Both at the outset of moving from suicidality, when some felt raw and unable to think clearly and at times when the motivation to be proactive flagged, during setbacks, times of adversity or distress, participants described saying to themselves “*I am not willing to give in*” (I 9), “*I will make this work*” (14), and “*Just put one foot in front of the other*” (I 15). This was an important strategy when all meaning had collapsed, when they no longer had their previous anchors, and had no comforting aphorisms or faith in a higher force. At this point, participants describe returning to a holding pattern, stabilizing through simplifying life and structuring the day.

Participants developed “mantras” or a litany to say to themselves at moments of hardship when they could not see through disappointment, despair, and exhaustion,

"I have survived before and I will again" (I 1); *"The bad times passed before and life was good again – this bad moment will pass and it will be OK again"* (I 11); *"I always find solutions"* (I 2; I 7; I 12); *"My children are watching and I will role model how to deal with hard times for their sake"* (I 6); *"Fake it until the feeling catches up"* (I 3; I 14); *"Pick some easy success and start rebuilding again"* (I 1; I 14); *"Its time for back to basics for a while – go to the gym, eat well, sleep"* (I 1); *"Don't give up until you have done one good thing"* (I 1); *"No point in tossing in the towel – you just have to pick it up again sometime"* (P 1; I 13); and *"Think of your impact on others . . ."* (11 participants).

They described self-talking, reminding themselves they could withdraw from stressors until they felt ready to face them, *"I am not obliged to be with this person just now, its OK to choose who, when, where . . ."* (I 2). They reminded themselves, *"I have got through hard times before – what tools did I use then?"* (I 1) When thinking further into the future just brought up feelings of terror, they allowed themselves to just deal with the next half hour, next five minutes – they used gentle distractions (I 14) – parented and comforted themselves (I 6). A number of participants reflected on what had made them feel good in the past. For some, it was being in nature, by the sea or in the sea (I 6); for others it was exercise (I 1; I 14); for two, it was a time of no thinking, just immersing their hands in the soil (I 4), and carting rocks, gardening (P 2). Several spent time with a pet and found comfort in the wordless company of their dog (I 4; I 10) – one bought a dog specifically to have simple company and a motivator to get out of bed in the morning and walk (I 4).

It was during acute distress, when needing to be indomitable, when structure to the day was important (I 2) and participants describe using a range of behavioral strategies, e.g., setting little achievable goals and tasks to build experiences of success and therefore optimism; setting up safety nets – calling support services, networks, friends, even stockpiling resources, e.g., a library of books/posters for when they cannot remember what steps help. One person described covering their home in post-it notes as reminders of comforting insights they had previously had. In the spirit of being their own therapist, best friend, or life coach – they celebrated little successes and progressively set new goals to stretch a little more each time – thus building confidence (I 4; I 12; I 13).

As the moment of acute distress stabilized, participants fostered dreams and reflected on how to achieve them. They once again began the cycle of reflection, problem-solving, and initiating actions for recovery and to resume rebuilding.

Choosing Happiness

Many participants, who survived trauma and abuse at the hands of others, believed that it was important to rediscover what was important to them, what they valued, and what choices they could make (I 6; I 7; I 9; I 12), and that this had been important in consolidating their recovery and reducing the risk of relapse to depression and suicidality.

Participants described how the opening of options did not, however, stop at resetting their career paths. Many participants referred to “*eliminating shoulds*” (I 6; I 9) and instead began to reconsider what they believed was important, based on their growing confidence in the moral compass they had developed for themselves. All participants spoke about the need for and the importance of “*your passion*” (I 5; I 14; I 15) – “*Find the things you are naturally gifted at – what passion would make you jump out of bed in the morning?*” (I 5); “*Making choices that will give happiness*” (P 2; I 1; I 5; I 9; I 10; I 11; I 14); and “*Get back in touch with what gives you life*” (I 15).

Making critical decisions to consolidate recovery and to go beyond survival to flourishing was not always easy. As all participants’ efforts to “*live more consciously*” increased their insight into the positive and negative drivers in their life, they described how they had needed to make difficult decisions to eliminate friendships that were destructive in their nature or that kept them linked to destructive or high-risk lifestyles. For some, it was necessary to distance themselves from some family members. At the same time, nine participants had eventually felt the need to reconnect with alienated family and shore up good friendships. Almost all participants spoke about being very selective about who they now allow into their intimate friendship circle, taking time to observe and decide on the trustworthiness of the person and/or their positive or negative impact.

Making a decision to change life/career trajectory was also challenging. Interviewee 14 described how he recovered from suicidality and in doing so found himself reflecting on “*what statement was I making?*” and then deciding instead to “*get successful, get even, get better.*” He ceased to try and fit into what he felt he should do, i.e., university and then teaching, and instead made the decision to pursue his creative passions becoming a performing artist, with mime, circus, theater, as a professional discipline and with great commitment. He is now an internationally renowned performer and runs master classes for other performers.

Choosing happiness was not always easy nor did it result in immediate reward, but some of the participants, like interviewee 14, explained that stepping outside their comfort zone and pursuing their passion brought with it a feeling of “*pressure having been removed*” and an excitement and satisfaction that were their own reward. Interviewee’s tips included – to “*access other parts of yourself*”; to “*give it all you have got*”; to be able to face uncertainty and feeling ill-equipped, “*but swim through it.*” Participants also described the self-care and supportive connections, which were important in this move beyond survival, knowing when to ask for help. It seems the skills they learnt to recover and rebuild armed them to go even further and take risks that could lead to them flourishing.

Participants had all spoken about having reevaluated the values, which underpinned their life decisions and becoming more focused and clear on their personal ethics. It seems that becoming clearer on their ethics was then a major contributor to enabling them to make decisions on life directions, which may not have been immediately popular with those around them. Participants described filtering decisions on what would give them happiness, through values that included

“do no harm,” and so they had confidence these courses of action were worthy of pursuit, even if they sometimes received early negative reactions from others.

Sustaining Resilience

Interviewees still had crises of confidence when new strategies did not work or other adversities arose, and they did from time to time succumb to self-flagellation and recrimination but described recognizing quickly each time that these were counter-productive and exhausting. They described that at these times they would once again make the choice to put in place the stabilizing behaviors and support in order to regain clarity and consider what next.

At the time of interviewing, some participants were facing major challenges in their health or were financially under a lot of strain; however, they still believed in their capacity to find solutions or to adjust constructively and were both pacing their way through these problems and ensuring they had opportunities for positive experiences and warm connections to keep some balance in their life experience. Interviewee 10 described using music and good company, going fishing to provide positive experiences and regain “*perspective*.”

On occasions, some participants would still begin to slide toward depression and/or suicidal ideation, but, as interviewee 10 described, “*I now recognise these as warning signs*” of exhaustion or of vulnerability through some other cause, and pull back into stabilizing patterns – exercise, good company or solitude, and then choosing activities at which they could succeed and regain confidence.

A lifestyle characterized by resilience and well-being did not mean a life free of suffering for participants – it meant confidence in their ability to get through any problem, to make choices that create positive experience and then optimize their options; knowing what gave them pleasure, comfort, delight, and ensuring those activities are part of their lifestyle; knowing when to retreat into self-care; and taking pleasure in volunteering or being engaged with their community. The cycles of reflection and action, which had become their default response, were helping them to continue generating a balance of protective factors and joy, in lives that are contemporarily as challenged as anyone, by everyday adversities.

Summary

How participants gave meaning to their experiences and rebuilt their framework of meaning and ethics for their next chapter in life was pivotal to driving the process of recovery. This was for two reasons. One was the capacity that participants demonstrated to live with a period of no meaning, when things they had believed in or on which they had previously based life’s major decisions collapsed and proved hollow. They demonstrated the importance of being able to survive day-to-day living, while consciously constructing a new framework of meaning on which to predicate reflection, decision-making, and action. As suggested in the review of resilience

literature earlier in this chapter, perhaps the search for meaning is as great an anchor as meaning itself.

The other way in which meaning was important to their recovery was that participants adopted an approach of reframing adversity into an opportunity to learn, taking an objective observer, problem-solving orientation.

It was notable that the decision to take control of the healing process appeared to be a turning point, which began the process of recovery for interviewees. It reflected a shift from believing they were at the mercy of external forces to an internal locus of control, where their shock at realizing how vulnerable they had become, to have become suicidal, became a motivator to recover and proactively rebuild their life and build life skills to prevent such decline ever again.

The 17 participants successfully managed to stabilize, either seeking someone with whom they felt safe and who comforted and/or supported them, or by seeking solitude and more anonymous connection. It seems that there were a number of decisions they made that galvanized their resolve that suicide was not an option and that if they were to avoid ever facing this level of trauma again, they would need to build on their existing strengths and learn the skills and ways of thinking that could move them through difficult times constructively.

This led participants to embark on a process of observation, reflection, analysis, and problem-solving to decide on what next step they needed and then designing a strategy to achieve that, including the resources, life skills, or support they might need to implement that next step. If the strategy worked, they consolidated for a time until they felt ready to take some new step or some adversity arose, which required their attention. If it did not, they framed it as an opportunity to learn.

Participants went through similar stages of recovery, during which they drew on all the range of resilience factors as and when needed to support their self-managed healing process. They all sought to first stabilize, then rebuild and eventually go beyond survival to making choices that enabled them to flourish. The resilience factors that participants drew on or actively sought to develop were all drawn on in different ways at different times, sometimes in combination, sometimes leveraging off one to strengthen another. Their movement through these was navigated by the habit they developed, pausing to avoid reactivity and then embarking on another cycle of reflection and action.

Participants described that depression and suicidal ideation could reemerge from time to time, but that they now saw it as a warning of exhaustion or vulnerability and a need to stabilize and implement self-care strategies. Participants described their lives as having gone beyond surviving through to thriving and characterized their life as one of well-being and resilience.

They demonstrated that it is possible to self-manage recovery from suicidality, and it is the process of self-managing recovery, itself, that builds the person's confidence in their capacity to always find solutions when faced with adversity.

I now know that I was able to deal with unbelievable (emotional) pain and therefore I can deal with anything. (I 15)

Abstract

Suicide is the third leading cause of death for 15- to 19-year-olds worldwide. Over one-third of adolescents who experience suicidal ideation (SI) eventually attempt suicide, typically within 1 to 2 years of the onset SI, and a prior suicide attempt is one of the best predictive risk factors for eventual death by suicide as well as future suicide attempts among adolescents. Thus, effective treatment of suicidal adolescents, especially those who have attempted suicide, is an important component of addressing the public health problem of youth suicide. In this chapter, we summarize recent reviews and meta-analyses of the literature on the treatment of suicidal adolescents. We then discuss the major treatment approaches, primarily dialectical behavior therapy, different variations of cognitive-behavioral therapy, and different family therapy models. A few other approaches with less support are also discussed including developmental group therapy, multisystemic therapy, and mentalization therapy. Although safety planning does not have stand-alone empirical data to date with adolescents, we also describe a typical safety planning session. We conclude with a discussion of ketamine as a psychopharmacologic treatment just beginning to be studied with adolescents as well as the use of digital technology to enhance the treatment of suicidal adolescents.

Treatment Approaches with Suicidal Adolescents

Introduction

Although data on international adolescent suicide rates is incomplete, the World Health Organization reports suicide as the third leading cause of death for 15- to 19-year-olds worldwide [1]. However, inconsistencies in suicide reporting and a dearth of information from underdeveloped countries have resulted in global estimates largely representing western, developed countries. An analysis of the World Health Organization (WHO) Mortality Database found a rising trend in deaths by suicide among youth aged 15–19 from 1965 to 1999 [2]. A later analysis of the database from 1990 to 2009 found rates among 15- to 19-year-olds were declining in western countries (including the United States), with South America showing the only significant regional rise, globally [3]. The most recent assessment from 2010 to 2016 expanded age criteria to 10- to 19 year-olds and found that, when controlled for age, adolescent suicide rates were slightly lower but overall consistent with those rates observed from 1990 to 2009 [4].

Suicide is the second leading cause of death among adolescents in the United States (US), with the CDC reporting in 2017 that 17.3% of deaths in youths ages 10–24 were due to suicide [5]. Girls have experienced a threefold increase in suicide deaths since

1999 [6]. Within the last decade, death by suicide among adolescents ages 15 to 19 has increased by one-third among males and doubled among females [7]. There has also been an increase in the suicide attempt rate among US adolescents, from 6.3% in 2009 to 8.6% in 2015 [8].

Over one-third of adolescents who experience suicidal ideation (SI) eventually attempt suicide, typically within 1–2 years of the onset of SI [9]. A prior suicide attempt is one of the best predictive risk factors for a future suicide attempts among adolescents as well as eventual death by suicide [10]. Approximately one-third of adolescents and young adults, ages 15–24, who died by suicide were found to have previously attempted suicide in a large psychological autopsy study [11]. Almost two-thirds of adolescents hospitalized for a suicide attempt reported a subsequent suicide attempt within 2 years of discharge [12]. Thus, effective treatment of suicidal adolescents, especially those who have attempted suicide, is an important component of addressing the public health problem of youth suicide.

In this chapter, we first summarize recent reviews and meta-analyses of the literature on the treatment of suicidal adolescents. We then discuss the major treatment approaches, primarily psychotherapy, to adolescent suicidal ideation and suicide attempts by highlighting recent, as well as representative, empirical studies of various therapies. We limit the literature review and our description of studies to those in which suicidal ideation and suicide attempts were a specific focus of treatment and one of the main outcomes.

Review of Recent Meta-Analyses

There have been several reviews of the literature on the treatment of suicidal adolescents in the past decade or so. These reviews consist primarily of psychotherapy studies because medications that specifically target suicidal ideation, with the exception of recent studies with ketamine (see below), have not been developed. Medications are instead typically prescribed to address an underlying psychiatric disorder, typically depression, presumed to underlie suicidal ideation and attempts.

The oldest meta-analysis reviewed here was published in 2008 and focused specifically on cognitive-behavioral therapy (CBT), or interventions that integrated CBT as a component of treatment, to reduce suicidal behavior, defined as death by suicide, suicide attempts, suicide intent, suicide plans, and/or suicidal ideation by the authors [13]. This review identified 6 adolescent and 18 adult studies. There was variability in the CBT techniques used, method of delivery, treatment setting, type of control group employed, and types of professionals who delivered the interventions. It is notable that the age ranges are loosely and inconsistently defined across studies. For example, one of the adolescent studies describes their sample as *older adolescent* with an age range of 18–24 years old, while another describes an adult sample of 15–18 years old. The authors of the meta-analysis chose to categorize studies based on the description of the sample rather than the age of participants in the original articles; thus, some adult studies were included in the adolescent category and vice versa. Overall, the meta-analysis concluded that CBT was effective in treating

suicidal behavior in adults but not adolescents, although the authors noted that further research would be needed to truly understand the utility of CBT among this younger age group given the dearth of research available at the time of their review.

Another meta-analysis for the US Preventive Services Task Force published 5 years later [14] focused primarily on the efficacy of screening for suicide risk in primary care. They also reviewed 11 RCTs conducted with adolescents that examined the effects of treatment on suicidal ideation and behavior. Treatments included CBT, developmental group therapy, attachment-based family therapy, and brief interventions. Similar to the Tarrier et al. [13] review, the O'Connor et al. (2013) review found that psychotherapy, broadly construed, reduced suicide attempts in high-risk adults, but not adolescents, and that there was a paucity of research assessing effective treatments for adolescents. Some limited findings suggested that interventions that targeted parents and youth together were more effective than those targeting youth alone.

A 2015 meta-analysis focused on youth suicide treatment evaluated treatment efficacy across 29 studies, including 18 randomized control trials [15]. The analysis used the Society of Clinical Child and Adolescent Psychology evaluation criteria for evidence-based treatments that categorize treatment approaches into levels of efficacy ranging from *Level 5: questionable efficacy* to *Level 1: well-established treatment*. The review found no treatment approaches met the criteria for *Level 1: well-established treatments*. The following treatments were found to be *Level 2: probably efficacious*: (1) CBT-individual + CBT-family + parent training for suicide attempts, (2) family-based therapy (FBT) – parent training, for self-injurious thoughts and behaviors (composite of non-suicidal and suicidal), (3) attachment-based family therapy for suicidal ideation, (4) interpersonal psychotherapy – individual for suicidal ideation; and (5) mentalization-based treatment for deliberate self-harm (composite of non-suicidal and suicidal self-injury). Multi-systemic therapy was classified as *Level 3: possibly efficacious* for suicide attempts. Due to an absence of completed randomized controlled trials (RCTs) evaluating dialectical behavioral therapy (DBT) at the time of publication, DBT was classified as *Level 4: experimental* for deliberate self-harm, non-suicidal self-injury, and suicidal ideation.

An update to the 2015 review was published in 2019 and compared the efficacy of 26 randomized control trials in youth [16]. Nine of these studies were new to the set evaluated in the previously discussed 2015 review. The primary new conclusion was the advancement of DBT from *Level 4: experimental* to *Level 1: well-established* for treatment of deliberate self-harm (composite of non-suicidal and suicidal self-injury) and suicidal ideation in youth. DBT was also deemed *Level 2: probably efficacious* for the treatment of non-suicidal self-injury and suicide attempts in youth. Additional updates included the addition of integrated family therapy as a *Level 2: probably efficacious* treatment for suicide attempts.

The latest review of evidence-based interventions for youth suicide reviewed in this chapter [17] also aimed to update the 2015 review by Glenn et al. This review similarly found DBT should be added to the classification of *well-established treatment*, as a result of two large randomized controlled trials completed within

the past 5 years [18, 19]. The authors also discussed the burgeoning importance of technology in adolescent treatment, reviewed studies that have attempted to deliver therapy to youth online (these studies are elaborated upon below), and suggested avenues for further research including wearable devices and crisis intervention through mobile applications.

Since the publication of the latest meta-analysis [17], there has been one additional published RCT testing CBT [20]. Although suicidal ideation and behavior decreased over the follow-up period, the treatment was not found to be superior to the treatment-as-usual (TAU) comparison group. This study is discussed in detail below.

Psychotherapy Treatment Approaches

In this section, we discuss the findings from selected empirical studies of the major psychotherapy approaches for suicidal adolescents. The treatment approaches that have the most studies and support are DBT, different variations and combinations of CBT, and different family therapy models. A few other approaches with less support are also discussed. We also present some details about safety planning. Although safety planning does not have stand-alone empirical data to date with adolescents, it has become standard in the United States for a safety planning session to be conducted with suicidal adolescents, regardless of the specific therapy approaches.

Individual CBT Approaches

Individual adolescent CBT approaches have been tested with the adolescent alone, with minimal parent involvement, but more commonly in protocols that have tested individual CBT with significant parent/family involvement and often pharmacotherapy. With respect to individual CBT for the adolescent, one of the first studies, conducted in the United States, compared CBT to supportive relational therapy (SRT) in a small clinical trial ($n = 35$) for adolescents who made a suicide attempt [21]. Both treatment protocols included ten treatment sessions delivered by one therapist, two treatment phases (3-month active, 3-month maintenance) and one conjoint family session. Sessions were attended weekly during active treatment and monthly during maintenance treatment. To control for therapist effects, seven different therapists provided both treatments. Both treatments resulted in equivalent reductions in suicidal ideation at the 3- and 6-month follow-up points. Two adolescents in SRT reattempted suicide over the course of 6 months while four adolescents did so in the CBT condition, but this difference was not statistically significant. A subsample (9 in each condition) was recontacted at 12 months, and no repeat attempts were reported in either condition. What sets this study apart from almost all other studies in the literature is that the same therapists conducted both treatment protocols. Therefore, the lack of differences across conditions can be attributed, at least in part, to therapist effects.

Recently, an Internet delivery of individual CBT, called Reframe-IT, was tested in Australia with high-school students (ages 14 to 18), recruited through their schools, who reported suicidal ideation. In pilot trials, Reframe-IT was determined to be safe and acceptable [22] and significantly reduced suicidal ideation in youth [23]. The pilot study was followed by a small RCT ($n = 50$) that tested the effectiveness of Reframe-IT plus TAU compared to TAU alone [24]. The intervention consisted of eight modules of CBT delivered online over 10 weeks with assessments conducted at baseline, 10 weeks and 22 weeks. Although there were reductions in suicidal ideation in both conditions, there were no statistically significant differences between groups at posttreatment or at 22-week follow-up. Two adolescents in the TAU condition, and none in the experimental condition, attempted suicide at the 22-week follow-up.

A small study in Sweden tested mood regulation-focused CBT (MR-CBT) ($n = 15$) compared to TAU ($n = 12$) in a group of depressed adolescents [25]. MR-CBT uses counter conditioning with memory reconsolidation in order to improve mood regulation. The adolescents practice reviewing emotionally positive memories to diminish the emotional impact of negative memories. Depression and well-being improved significantly in both treatment groups. There were no suicidal events at the end of treatment in the MR-CBT group, but three adolescents reported suicidal events in the TAU group.

Individual CBT + Parent/Family Involvement

CBT trials for suicidal adolescents are more commonly conducted with accompanying parent and/or family sessions than with an adolescent alone. One study in the United States [26] tested whether CBT for depressed adolescents with concurrent CBT treatment of a depressed parent (called parent-adolescent CBT; PA-CBT; $n = 16$) was more effective than CBT for adolescents only (AO-CBT; $n = 8$). In order to qualify for the study, adolescents had to meet criteria for a current major depressive episode, and the parent had to meet criteria for current or past major depressive episode. PA-CBT was more effective in reducing adolescent depressed mood than AO-CBT at the end of the active treatment period (24 weeks) but not at the 48-week follow-up. The effect at 24 weeks was stronger for parental depressed mood than adolescent depressed mood. A reduction in adolescent and parent suicidal ideation was found at both follow-up points but did not differ across conditions.

A more intensive treatment protocol, integrating CBT and motivational interviewing (MI) techniques for the adolescent, as well as parent and family sessions, entitled integrated-CBT (I-CBT), was conducted in the United States to address suicidal ideation and attempts in adolescents with co-occurring substance use and psychiatric disorders [27]. Adolescents ($n = 40$) were recruited at discharge from a psychiatric inpatient unit and randomized to outpatient I-CBT or enhanced-TAU (E-TAU). Two therapists (one who worked with the adolescent and one with the parents) were assigned to each family. Adolescent sessions were offered weekly during the first 6 months, biweekly during a 3-month continuation phase, and

monthly for another 3 months. Parent sessions were somewhat less frequent and varied according to the needs of the parents. The I-CBT protocol offered a menu of individual adolescent cognitive-behavioral (e.g., problem-solving, emotion regulation, behavioral activation), family (e.g., communication), and parent training (e.g., monitoring, behavioral contracting) sessions. Adolescents in both conditions were also offered medication management. At 6-month follow-up, suicide attempts were significantly lower in I-CBT compared to E-TAU (5% vs. 35%). In addition, there were fewer psychiatric hospitalizations in the I-CBT condition compared to E-TAU at the 6-month follow-up (18 months post-baseline). Comparable reductions were evident across conditions in SI, but these reductions did not differ across conditions.

In an extension of I-CBT (described above), 147 adolescents and their families, recruited from inpatient and partial hospital psychiatric programs, were randomly assigned to a modified I-CBT protocol call family-CBT (F-CBT) or enhanced-TAU [20]. Changes to I-CBT included modifications to sessions to better address emotion regulation (distress tolerance), physical health (healthy lifestyle), trauma (trauma narrative), and anxiety (exposure). Parental “self-care” sessions and a parental emotion coaching session to improve parent-child interactions were also added. Both conditions resulted in reductions in suicide attempts, suicidal ideation, and non-suicidal self-injury, but there was no difference between conditions. In the sample as a whole, rates of attempts decreased from 20% at 6 months to 9% at 12 months to 7% at 18 months.

CBT + Pharmacotherapy

Only a few studies have specifically examined the effects of pharmacotherapy on suicidal ideation and attempts in adolescents. Only one was specifically designed to address adolescents with suicidal behavior. The multisite Treatment of Adolescent Suicide Attempters (TASA; [28]) assigned 124 depressed American adolescents who made a suicide attempt in the prior 90 days into antidepressant medication only ($n = 15$), cognitive-behavior therapy for suicide prevention (CBT-SP) ($n = 18$), or medication plus CBT-SP ($n = 93$). Treatment assignment was random at the beginning of the study, but due to difficulties in recruitment, participants were given their choice of treatment assignment for the majority of the study, resulting in the imbalanced sample size across conditions. The goal of CBT-SP was harm reduction and relapse prevention. CBT-SP focused on developing cognitive, behavioral, and interpersonal skills to more effectively cope with stressors that might trigger suicidal crises and reduce the likelihood of further suicidal behavior. Parents also had family sessions focused on suicide risk reduction strategies. Individual adolescent and conjoint parent-adolescent sessions were available for up to 22 sessions over a 6-month period. All adolescents showed a significant decline in suicidal ideation at the end of treatment. With respect to suicide attempts, approximately 12% of the adolescents reattempted suicide, and 19% experienced a suicidal event (suicide attempt, suicide completion, preparatory acts toward suicidal behavior) at follow-up. There were no differences in suicide attempts or events across the three conditions [28].

Two other large multisite studies of depressed adolescents, both conducted in the United States, have examined suicidal ideation and behavior as primary outcomes. In the Treatment for Adolescents with Depression Study (TADS; [29]), depressed adolescents (30% of whom had clinically significant suicidal ideation at baseline) were randomly assigned to one of three active treatment conditions: fluoxetine therapy ($n = 109$), CBT ($n = 111$), or combination therapy ($n = 107$). Families could attend 15 sessions during the first 12 weeks, weekly to biweekly sessions during the next 6 weeks, and booster sessions every 6 weeks thereafter. The CBT intervention included both individual adolescent and conjoint parent-adolescent sessions. Reductions in suicidal ideation were greater for youth randomized to CBT or combination therapy than fluoxetine therapy alone. Adolescents in the fluoxetine-only condition were twice as likely to experience a suicidal event during treatment (14.7%) than those who received CBT (6.3%) or combination therapy (8.4%).

In the Treatment of SSRI-Resistant Depression in Adolescents study (TORDIA; [30]), depressed adolescents who failed to respond to a previous trial of a selective serotonin reuptake inhibitor (SSRI) antidepressant were randomized to one of four conditions: change to a different SSRI ($n = 85$), change to a different SSRI plus CBT ($n = 83$), change to venlafaxine ($n = 83$), or change to venlafaxine plus CBT ($n = 83$). Many of these adolescents had clinically significant suicidal ideation (58.5%) and prior suicide attempts at baseline (28.7%). The CBT protocol included 12 sessions conducted over the course of 3 months; the majority of sessions were with the adolescent alone but 3–6 of the sessions could be used as family sessions, depending on the needs of each family. Maintenance sessions were conducted during months 3–6. Suicidal ideation decreased across all conditions by the final follow-up point at 12 months. Approximately 20% reported a self-harm-related event (suicidal ideation requiring an emergency evaluation, suicide attempt, self-injurious behavior) during treatment, but there were no differences across conditions.

Dialectical Behavior Therapy

DBT is a multicomponent treatment that emphasizes treatment engagement and the reduction of non-suicidal self-harm and suicide attempts by teaching skills for enhancing emotion regulation, distress tolerance, and interpersonal effectiveness [31]. There have been several studies with adolescents that have produced promising results.

Rathus and Miller [31] used a quasi-experimental design to compare the efficacy of DBT-Adolescent (DBT-A) compared to TAU for suicidal adolescents; approximately one-third of this US sample reported a prior suicide attempt. Adolescents in both DBT and TAU attended approximately 24 therapy sessions over 3 months. The full DBT-A treatment package included weekly individual therapy, weekly multi-family group skills training (i.e., mindfulness, emotion regulation, distress tolerance, and interpersonal effectiveness skills), telephone coaching with the therapist when needed, and weekly consultation among the treatment team. The DBT group had

fewer psychiatric hospitalizations during the treatment period and higher rates of treatment completion than the TAU group. About 40% of adolescents reattempted over the course of treatment. No differences in repeat suicide attempts were found.

Mehlum and colleagues [18] published the results of the first RCT comparing DBT-A with an enhanced form of usual care treatment (eUC), consisting of 19 weeks of standard, non-manualized treatment. Of the 77 British adolescents recruited, about one-quarter had attempted suicide in the 4 months prior to enrollment, and all of the suicidal adolescents had at least two occasions of self-harm, either suicidal or non-suicidal. The DBT condition demonstrated statistically significant decreases in suicidal ideation and self-harm behavior compared to the eUC condition at the completion of treatment [18]. In addition, adolescents in the DBT, compared to eUC, had a greater decrease in the frequency of self-harm 1 year following treatment completion [18] as well as at the 3-year follow-up [32].

McCauley and colleagues [19] extended the findings of the British group in a US study. Suicidal adolescents ($n = 173$) with one lifetime suicide attempt, elevated suicidal ideation, and repeated self-injurious behavior were randomized into DBT or a comparison condition. The comparison condition consisted of a manualized client-centered treatment that had the same structure as DBT, in terms of modes of treatment (both group and individual) and number of sessions but used supportive therapy. From baseline to the end of treatment at 6 months, 9.7% of adolescents in the DBT condition attempted suicide compared to 21.5% of the adolescents in the supportive therapy condition. However, there were no significant between-group differences at the 1-year follow-up; adolescents in both groups improved following completion of treatment. DBT did have significantly higher rates of adolescents who did not have any self-harm at both the 6- and 12-month follow-up points.

Family Therapy

Elements of family life are important as both risk and protective factors for adolescents who self-harm. It has been found that, more so than any inherited risk, family interactional factors are strongly associated with self-harming behaviors in adolescents [33]. In family therapy, treatment is directed at maximizing family cohesion, developing supportive and warm parent-child relationships, and minimizing negative factors (e.g., maltreatment, ineffective parental control). Variations of family-focused therapy have been proven to be effective in reducing self-injurious thoughts and behaviors in adolescents.

Basic Family Therapy

Two trials have assessed stand-alone family interventions specifically targeting self-harm behaviors. Harrington et al. [34] conducted the first randomized trial evaluating a family-focused treatment program with suicidal adolescents in the United Kingdom. A total of 162 adolescents (10–16 years old) with a prior suicide attempt by

overdose were randomized to receive either routine care ($n = 77$) or routine care plus a four-session home-based family intervention ($n = 85$). The intervention focused on discussion of the suicide attempt, developing stronger communication and problem-solving skills and psychoeducation. The trial revealed some positive effects of the intervention with participating youth who were not also diagnosed with major depression: at 6-month posttreatment, there were greater reductions in suicidal ideation in this group compared to routine care alone. However, there were no overall differences between treatment groups on subsequent suicide attempts. Approximately 15% of the sample had made one or more attempts during the 6-month follow-up period.

The second and more recent trial, conducted by Cottrell et al. [35], was a large, multi-site study conducted in the United Kingdom leveraging the SHIFT intervention (Self-Harm Intervention: Family Therapy; [36]). Participants were 832 adolescents who had been referred to mental health services for repetitive self-harm (suicidal and/or non-suicidal self-injury) and their families. Families were randomized to either the SHIFT treatment condition or community TAU. SHIFT consisted of approximately eight 75-minute sessions spanning 6 months. Sessions focused on enhancing family's strengths and resources [36]. SHIFT was not significantly more effective than community TAU in reducing deliberate self-harm in youth at the 18-month follow-up appointment. There were significantly larger reductions in suicidal ideation for the SHIFT group at the 12-month follow-up, but the effects of treatment did not persist at 18 months.

Attachment-Based Family Therapy (ABFT)

Attachment-based family therapy (ABFT), a family-oriented psychodynamic therapy, focuses on the need and desire for a secure parent-adolescent relationship. Treatment is aimed at cultivating trust between the parent and adolescent so that the adolescent develops greater self-confidence. Two RCTs have assessed the efficacy of ABFT in treating suicidal thoughts and behaviors. Although the first RCT [37] presented promising results, these findings were not replicated in the second [38].

The initial randomized trial conducted by Diamond et al. in 2010 [37] evaluated the effectiveness of ABFT for American adolescents with clinically significant suicidal thoughts and depressive symptoms. A total of 66 adolescents and their families were randomly assigned to receive either ABFT ($n = 35$) or enhanced-TAU ($n = 31$). The study is notable because unlike virtually every study in the literature, the sample in this study was largely African American (70%). Sixty-two percent of participating youth reported a prior suicide attempt. Youth suicidal ideation and behavior were assessed both during the treatment phase of the study and in the 3-month posttreatment. Treatment engagement was found to be higher for those assigned to ABFT ($M = 9.7$ sessions, $SD = 5.23$; *v.* *e*-TAU $M = 2.9$ sessions, $SD = 3.3$). Youth in the ABFT condition exhibited a relatively faster reduction in suicidal ideation during the treatment phase of the study, though this trend did not persist at the 3-month posttreatment follow-up. However, a greater proportion of youth

in the ABFT condition exhibited suicidal ideation scores in the normative range at both the end of the treatment phase and at the 3-month posttreatment follow-up.

In 2019, Diamond et al. [38] published a replication of the first RCT, finding that ABFT did not perform better than enhanced-TAU in reducing suicidal ideation and depressive symptoms. In this larger trial ($n = 129$) conducted in the United States, youth received treatment for 16 weeks. About half of the families in the sample were African American. Youth in the ABFT ($n = 66$) condition showed equivalent decreases in suicidal ideation as youth in the control condition ($n = 63$) during the treatment phase of the study. Outcomes of the 9-month posttreatment phase have not been reported as of yet.

Integrated Family Therapy

Based on social-ecological cognitive-behavioral theory, integrated family therapy (IFT) combines techniques from CBT and DBT to strengthen the protective elements of the family context and other immediate social systems while also teaching new skills to cope with and manage behavioral issues and stress within the family.

An RCT conducted by Asarnow et al. [39] in the United States assessed the utility of an IFT program – the SAFETY (Safe Alternatives for Teens and Youth) treatment program – relative to enhanced-TAU. Over the course of 12 weeks, treatment was administered by two therapists – one each for the youth and parent. The program was tailored to each family using techniques such as a functional, or chain, analysis (which identifies the antecedents of the initial suicide attempt or self-harming behaviors). Therapists worked with the youth and parent to develop skills and techniques to improve emotion regulation and to foster a supportive environment. There was a strong emphasis placed on identifying barriers to treatment and creating a plan to reduce those barriers. Participants in this trial were 42 self-harming youth (11–18 years old) and their families who were recruited through either the emergency department, inpatient/partial psychiatric hospitalization, or outpatient services. Youth were deemed self-harming based on either a suicide attempt or non-suicidal self-injury within the past 3 months *and* repetitive (≥ 3) episodes of self-harm in their lifetime. A total of 20 youth were randomized to receive SAFETY, and 22 received enhanced TAU. Youth in the SAFETY condition were found significantly more likely than the youth in the TAU condition to not have an additional suicide attempt at the 3-month follow-up; of the six suicide attempts reported, all were from youth in the enhanced TAU condition.

Brief Family-Based Therapy

Brief family-based therapy (previously known as family-based therapy – emergency interventions) is a family-focused intervention delivered in moments of acute need in the emergency department. Two RCTs, both conducted in 2011, have assessed the efficacy of this intervention [40, 41].

The larger of the two trials was conducted in the United States and randomized 181 youth presenting to the emergency department with a suicide attempt or suicidal ideation to either receive a Family Intervention for Suicide Prevention (FISP) or emergency department TAU [40]. FISP included a family-based cognitive-behavioral therapy session and 1 month of follow-up contact over the phone to enhance the likelihood participants would follow through on recommended treatment. The intervention was successful at increasing treatment follow-through but was not significantly more effective at reducing future suicide attempts or suicidal ideation than emergency department TAU.

The second trial, conducted in the United Kingdom, assessed the efficacy of a family-based intervention in the emergency department among youth with recent deliberate self-harm behaviors ($n = 70$) relative to emergency department TAU [41]. The intervention included motivational enhancement and a cognitive analytic therapy assessment of the youth's self-harming behaviors. As in the larger trial by Asarnow, the intervention improved treatment adherence but had no incremental effect on reducing youth suicide attempts or suicidal ideation in the 2 years following the intervention.

Parent Training

Parent training is a brief intervention with the parents of youth exhibiting suicidal behavior. It is important to note that youth involvement in this intervention is extremely minimal and therefore it is not, *per se*, a family therapy. However, because of its focus on family functioning when working with the parent, we are including it in this section.

There has been one RCT [42] examining the efficacy of a parent training intervention. The Resourceful Adolescent Parent Program (RAP-P) was assessed with 48 suicidal adolescents and their parents in the United States. Families were randomized to either RAP-P or routine care. Routine care consisted of crisis management and safety planning. The RAP-P intervention was composed of four sessions which included family psychoeducation about self-injurious thoughts and behaviors, parent training, and strategies about addressing family conflict. Compared to youth in the routine care condition, youth in the families receiving RAP-P reported fewer self-injurious thoughts and behaviors over the course of treatment as well as the 6-month follow-up period. The significant intervention effects were fully mediated by improved family functioning.

Safety Planning

Safety planning is a brief suicide intervention originally developed for use with patients in acute care settings [43] and adapted for use with suicidal adolescents [44]. Safety planning was cited as a best practice by the Suicide Prevention Resource Center/American Foundation for Suicide Prevention Best Practices Registry for Suicide Prevention (www.sprc.org). Although it has not been tested as a standalone

intervention, it is discussed here because it is so frequently used in a broad range of treatments for suicidal adolescents and is considered part of standard care in the United States.

Safety planning as an element of treatment has been assessed with adolescents in several RCTs, including the TASA, FISP, and SAFETY interventions previously discussed in this chapter [40, 28, 39]. A pilot study conducted in 2018 evaluated the feasibility and acceptability of a motivational interview enhanced safety planning intervention (MI-SafeCope; [45]) among teens hospitalized due to suicide risk. A total of 36 hospitalized adolescents (30.6% attempted suicide in the past month) were randomized to MI-SafeCope or TAU. MI-SafeCope was shown to be both feasible and acceptable. Additionally, the intervention was found to increase youth self-efficacy in safety plan use and refraining from future attempts. Unfortunately, the TAU condition also included safety planning, so it is not possible to assess the efficacy of safety planning specifically.

A recent pilot open trial [46] assessing safety planning among youth in the juvenile-justice system found promising preliminary effects of the safety planning intervention. A group of 15 justice-involved youth and a parent-guardian were assessed. Youth were eligible for the study if they endorsed suicidal ideation or scored above clinically significant levels on the subscales of the Massachusetts Youth Screening Inventory-Version 2 (MAYSI-2; [47]). Slightly more than half of the youth endorsed suicidal ideation (53.3%). Suicidal ideation decreased from pre-intervention baseline to 3-month follow-up.

The safety planning intervention is based on the principles of cognitive-behavioral therapy. It is designed to help youth identify warning signs of their own emotional dysregulation and to create a personalized list of coping mechanisms and social supports for use prior to or during moments of crisis. The intervention is completed between the youth and a therapist. The youth's parent or guardian is typically brought into the discussion after the plan has been created to review and discuss how to best facilitate the plan. A key element of parental involvement is making the environment safe. Safety planning places a large emphasis on restricting access to means because accessibility to means has been shown to be a distinguishing factor between youth who are hospitalized for suicide risk and youth who are successful in completing suicide [48, 49]. Engaging parents in conversation about their role in facilitating their youth's safety has been shown to increase the likelihood that they follow through on restricting access to means [49].

The safety planning process, as practiced by the authors of this chapter, starts with the therapist asking the youth to identify warning signs or triggers to their suicidal crises. These could take the form of thoughts (e.g., "I hate myself"), behaviors (e.g., self-isolating), emotions, (e.g., hopelessness), or somatic symptoms (e.g., adrenaline rush, shakiness). If possible, it is recommended that therapists prompt youth to identify a warning sign that others, like a parent or guardian, may be able to observe about them in addition to internal warning signs.

In the next step of developing the safety plan, the youth and therapist come up with possible behavioral and cognitive strategies that the youth can utilize on their own once they begin to experience warning signs. These coping skills involve things

like reading, listening to music, going for a walk, deep breathing, etc. Importantly, these strategies are something the youth is able to do on their own. Given the diverse contexts a youth experiences throughout the day – school, home, work, etc. – it is helpful for at least one of these coping mechanisms to require no additional materials. For example, watching TV is not something that would be accessible if a crisis were to occur at school; however, going for a walk or deep breathing would be more feasible in this context.

Next, the youth and therapist identify strategies that leverage the youth's support network. Three groups of people are identified: (1) those who could be helpful in distracting the youth without having to necessarily discuss their situation, e.g., friends; (2) those who the youth could turn to for explicit help in managing their feelings, e.g., a parent or guardian; and (3) emergency contact numbers, e.g., crisis hotlines, their therapist's number, etc. In the event a youth does not feel comfortable including a parent or guardian in the second category, the therapist will work with the youth to identify at least one responsible adult they can include.

Once completed, a hard copy of the plan is kept by the youth and the therapist. A picture of the plan is also taken on both the adolescent's and the parent/guardian's phone. The safety plan is intended to be fluid and adaptable. Therapists will follow up with the youth in regular sessions to ensure the plan continues to be useful and effective for them.

Other Psychotherapies

There have been several other approaches to the treatment of suicidal adolescents with less testing and empirical support in the literature. Three programs are reviewed here.

Multisystemic Therapy (MST)

Multisystemic therapy (MST) is an intensive home-based, family-focused intervention targeting problem behaviors of adolescents at multiple levels, including peers, family, school, and community [50]. A variety of behavioral interventions are typically delivered in MST based on a set of nine treatment principles. MST leverages a home-based service model and therapists with low caseloads to deliver intensive treatment over a 3- to 5-month period (in some cases, contact with the therapist is daily). High levels of family engagement and success in modifying risk factors have been demonstrated [51, 52]. MST has been found effective with high-risk and complex need populations, such as juvenile justice-involved youth.

Only one trial has assessed the utility of MST in treating self-harm behaviors. Huey et al. [53] randomized 156 youth in the United States who had been approved for emergency psychiatric hospitalization due to a threat of harm to themselves or others (i.e., suicidal ideations/planning, suicide attempt, homicidal ideation, or

behavior, psychosis). Approximately half of the participants were classified as suicidal (51%; $n = 80$). Families were recruited at the hospital's emergency department and randomized to receive either MST or the hospitalization condition. Adolescents who received MST reported fewer suicide attempts over the course of treatment compared to those who received hospitalization. Suicidal ideation improved for both groups over the 1-year follow-up, but there were no differences between the two groups.

Developmental Group Therapy

Developmental group therapy as an adjunctive treatment has been tested with adolescents who self-harm in three British clinical trials. In the first trial, 63 adolescents, who had deliberately harmed themselves on at least two occasions within a year, were randomized to group therapy plus routine care or routine care alone [54]. The group therapy approach utilized techniques from a variety of theoretical orientations, including cognitive-behavioral and DBT techniques. The group intervention consisted of six structured "acute" group sessions, followed by weekly process-oriented long-term group therapy. Adolescents who received group therapy plus routine care compared to routine care alone were less likely to make more than one repeat suicide attempt (2/32 versus 10/31; odds ratio 6.3) at 6- to 7-month follow-up. However, two replication trials of developmental group therapy as an adjunct to TAU did not result in greater improvement in self-harm or suicide attempts [55, 56].

Mentalization Therapy

Rossouw and Fonagy [57] randomized 80 adolescents (80% with a lifetime history of suicide attempts) to mentalization-based treatment (MBT-A) or TAU. MBT-A is a year-long individual psychotherapy based on psychodynamic theory. Participants in the MBT-A condition had larger reductions in self-harm, with 56% reporting a suicide attempt in the MBT-A condition compared to 83% in TAU at the 12-month follow-up. However, only 37 participants (46%) completed treatment across both conditions.

Brief Integrated Interventions Used in Inpatient Settings

There have been a few attempts to develop interventions specifically targeted to suicidal adolescents prior to their discharge from an inpatient psychiatric admission. This group has been targeted because one-third to one-half of psychiatrically hospitalized youth in the United States are readmitted for a psychiatric emergency, with the highest readmission risk within a month of discharge from the hospital and more than 80% of readmissions occurring within 3 months [58, 59]. Kennard et al. [60]

conducted a brief intervention during hospitalization and then used a phone app to support this work after discharge with 66 adolescents hospitalized for suicidal ideation or a recent suicide attempt. The adolescents were randomly assigned to the experimental intervention (As Safe as Possible – ASAP) plus TAU or TAU alone. ASAP consisted of four modules delivered during hospitalization using a motivational interviewing style. The module content included psychoeducation, behavioral activation, distress tolerance, increasing positive affect, safety planning, and skill review/skill consolidation. The safety planning intervention took place during hospitalization and after discharge using a phone app. The app “pushed” daily text messages asking adolescents to rate their level of emotional distress. Based on their level of distress, adolescents could receive a range of distress tolerance and emotion regulation skills, tailored to individuals. At the highest distress levels, the app presented the safety plan, included reminders to seek interpersonal support, and prompted the adolescent with clinical contact information. ASAP was found to have a greater decrease in suicide attempts over a 6-month follow-up period compared to TAU (16% versus 31%), but this difference was not statistically significant. There were no between-group differences on suicidal ideation. The majority of youth reported using the phone app after discharge.

Another study [61] collected data on 463 adolescents who had received a brief adjunctive intervention, the Coping, Problem solving, Enhancing life, and Safety planning (COPEs) treatment protocol, during a psychiatric hospitalization. Adolescents received psychoeducation and skills training from a multidisciplinary team that focused on enhancing safety and improving coping skills and problem solving around the factors that led to hospitalization. The coping plan module provided a list of regulatory strategies, including things they could say to themselves and things they could do to feel better. The problem-solving module helped teens identify the triggers that led to the hospitalization and ways to address these issues if they were to arise again. The third module focused on enhancing life by taking medication, healthy eating, engaging in pleasant activities, and improving sleep. The protocol concluded with a safety plan. Completion of the four modules in COPEs, particularly modules on developing a safety plan and enhancing life, predicted lower rates of rehospitalization and emergency department visits in the 12-month post-discharge.

Technology as an Aid in Treatment

Utilizing technology to broaden the scope and efficacy of suicide prevention has been a topic of interest for at least the last decade [62, 63, 64]. Given the extent to which adolescents engage with technology on a daily basis – 95% of US adolescents either own or have access to a smartphone and 45% report a constant online presence [65, 66] – leveraging these mediums to reach youth is a natural advance. In light of the global coronavirus pandemic, the need for such an advancement has become immediate.

After the pandemic onset, several articles were published on the importance of telemedicine and the clear need for further research to understand its costs and benefits [67, 68, 69]. There are no studies yet assessing youth suicide outcomes posttreatment by telemedicine. One study in the United States assessed the feasibility of telemedicine as an alternative to in-person crisis evaluations of youth who presented with mental health concerns to the emergency department [70]. The aim of the study was to consider telemedicine as a potential solution for provider shortages in rural areas. Almost half (47%) of the youth in the study presented with suicidal ideation or self-harming behaviors. The psychiatrist who conducted the telemedicine crisis evaluation was assisted by a nurse in the ED who prepared the discharge note as well as a safety plan for the adolescents and their families upon discharge. The authors concluded that telemedicine crisis evaluations of youth are feasible but that significant resources are still needed to successfully implement telemedicine in the emergency department.

In general, research on technology-based suicide prevention and therapy with youth is extremely limited. A review conducted in 2016 [64] found that there was only one RCT assessing online suicide prevention with youth (Reframe-IT – elaborated upon in an earlier section of this chapter; [24]). A more recent review of RCTs, pilot RCTs, and open trials examining suicide interventions delivered through mobile devices was conducted in 2020 by Melia and colleagues [71]. Of the seven studies assessed, only one was focused on adolescents. The open trial was conducted in the United Kingdom by Stallard et al. [72] and assessed the efficacy of a smartphone app, BlueIce, in helping youth to manage stress and reduce the urge to self-harm. The study found that 73% of youth who had disclosed recent self-harm at the beginning of the study reported reductions in self-harm behavior after 12 weeks of using the BlueIce application. Significant reductions in antecedents to suicide (e.g., depression, anxiety) were also reported. The app used in this British study is similar to the one used by Kennard et al. [60], described above, after discharge from inpatient care in her multicomponent intervention.

Rapid Acting Treatments for Severe Suicidal Ideation: Ketamine

Ketamine infusions and intranasal esketamine have been shown to result in significant reductions in suicidal ideation within 1 day and lasting for 1 week in adults [73]. Although ketamine has been safely used for anesthesia in youth for many years, studies with suicidal youth have just recently appeared. One open trial with adolescents has been reported in the literature. Thirteen adolescents with treatment-resistant depression received 6 ketamine infusions (0.5 mg/kg) over 2 weeks. Improvements in depression were noted in 6 adolescents and 3 of the responders remained in remission at the 6-week follow-up [74]. The responders also reported a reduction in suicidal ideation. Single case studies of adolescents with treatment-resistant depression ([75] and psychotic depression [76]) have reported positive results on suicidal ideation. Thus, ketamine may have a role in treating suicidal adolescents, but its use in clinical care will need to await testing in RCTs.

Conclusions

Over the past decade, there has been some progress in the treatment of suicidal adolescents. The psychotherapy approach with the best findings to date with respect to reducing continued suicidal ideation and behavior is DBT. However, DBT is the most intensive and expensive treatment that could be delivered and thus is not an option for many families. In addition, due to its expense, DBT is not typically considered a first-line treatment for suicidal adolescents. Therefore, the core treatment techniques that have been used across the various treatment approaches in the literature should be considered by therapists in working with suicidal adolescents. The typical safety plan includes two core components for successful treatment of suicidal adolescents, emotion regulation skills, and seeking effective interpersonal support. These skills should be part of any psychotherapeutic approach with suicidal adolescents. In addition, addressing dysfunctional cognition is important for many suicidal youth and is a standard skill taught in CBT protocols. Working with parents/guardians is also an essential part of any psychotherapy protocol.

The burgeoning use of technology in mental health care promises to change the way we treat suicidal adolescents in the next decade. Whether it be providing easy access to therapeutic techniques via a phone app when a teen is in crisis or reminding adolescents of emotion regulation skills and cognitive techniques to reduce suicidal thinking before they reach crisis levels, technology is here to stay. These technological interventions need to be empirically tested to determine whether their promise will meet our expectations. In particular, it will be important to conduct studies on how to increase the use of these apps by adolescents, especially during crisis periods. Finally, ketamine is the first advance in the psychopharmacologic literature in decades. Ketamine has shown promise in the treatment of adults, particularly those with treatment-resistant depression and suicidality. Whether it will prove effective with adolescents will be determined by future RCTs. Regardless, it will not replace psychotherapy but rather, at best, should be considered a component of a combination therapy to treat our highest at-risk suicidal adolescents.

Abstract

Late-life suicide constitutes a serious public health problem. Globally, older adults experience very high suicide rates nearly everywhere. The aging process influences suicidal behavior by posing to individuals several different types of challenges, such as physical frailty, dependence, losses, etc., making of suicide in old age a phenomenon with peculiar characteristics. This chapter proposes an overview of epidemiological data with risk and protective factors, and specifically analyzes universal, selective, and indicated prevention interventions for this population group.

Old age · Epidemiology · Suicide · Risk factors · Prevention

Introduction

The World Health Organization (WHO) defines the threshold to becoming an “old” person the age of 65 [176], using life expectancy at birth as the main parameter. Globally, the significant disparity in life expectancy rates between high-income (80 years) and low-middle-income (57 years) countries and the higher population density of the latter group [179] would tend to a downward remodeling of that threshold. However, the WHO indication considers the progressive improvement in quality of life [177] and demographic projections, which anticipate a rapid increase in the older adults’ population worldwide [178].

From a psychological point of view, older persons reach a stage in their life path that places them in front of a fundamental evolutionary task: to complete and consolidate the sense of ego integrity or to succumb to a meaningless and unworthy conception of life being lived to the point of despair [55]. In this particular age group, this “psychosocial dilemma” influences the profound difference between sadness and depression, and healthy aging and ageist perspectives, which associate old age with an inevitable deterioration of physical and mental abilities [135].

Furthermore, the concept of old age takes on very different connotations based on the individual lifestyle [10], the representation and social role attributed to it by the community [35, 174], and the cultural meanings of the different contexts of reference [115].

In this sense, old age is to be understood as a social construct [87], underlying numerous evolutionary and biological [32], social and psychological [131], and historical, cultural, and demographic factors [10, 87].

These considerations about the aging process help to understand the peculiarities of suicidal behavior in later life. In general, when suicidal, older adults seem to be guided by a rational decision [35], given the fact that suicide attempts are less frequent than in younger age groups [42, 93] and the choice of means falls within the most lethal ones [77].

However, although suicidality is placed on a continuum with different risk levels [136] determined by distal and proximal factors [96], suicide in old age is a heterogeneous phenomenon [93] that fluctuates over time [39]. Proof of this is the numerous studies that have analyzed, in this population segment, the characteristics of the age subgroups [93], gender differences [35, 96], prevalence of some risk factors over others and their modification over time [77], need to identify protective resources [80], and specific preventive programs [96].

Epidemiological Data

In recent decades, medical advances in rehabilitation and the expansion of health care have made it possible to limit functional impairment and disability in the old-age population [23, 105]. Furthermore, investment in socioeconomic policies aimed at protecting old age and improving social security [43] has significantly contributed to the globally increased life expectancy [177].

Consistent with these observations, suicidal mortality rates have decreased by about a third in the general population [65], particularly in old age [11]. However, the data reported by the studies of the Global Burden Disease [65, 66] show that suicide in older adults still registers age-standardized rates among the highest in the world: 11.1 per 100,000 for the general population, against 27.45 per 100,000 in the over 70s, and 16.17 per 100,000 in the 50–69 years of age range. Furthermore, suicide mortality appears to worsen with age, with the highest prevalence among people aged 85–89 years [147].

In addition to epidemiological data, there are concerns about the rapid increase in the old-age population globally, which by 2050 is expected to double: from 12% to 22% [178], reaching 2.1 billion individuals [159]. These data are alarming when considering geographical areas such as Europe and the United States, where there are the highest suicide rates among high-income countries [21, 59, 73].

In particular, Eurostat predicts that by 2080 older people in Europe will represent about one-third of the population, reaching almost 149 million individuals [58]; while in the United States, a fifth of the population in the next decade will be 65 years of age or older, with a current average of 18 old adults' suicides every day [122].

In addition, the imminent entry of baby boomers into old age, accompanied by their particular propensity for suicidal behavior [27], further leads to consider suicide in late life as a major public health concern [147].

Finally, it is necessary to keep in mind that the data from official statistics, in addition to being susceptible to numerous registration biases [123, 173], most probably represent only partially the real epidemiological dimension of the suicide phenomenon, especially for older adults [35]. For example, in the United States, it has been estimated that over 40% of late-life suicide may go undetected due to “silent” suicides, such as deaths from overdoses, self-starvation or dehydration, and “accidents” [6].

Risk Factors

While demographics provide the main information on nonmodifiable risk factors for suicide, such as age, sex, race, and ethnicity [22], retrospective research is the most frequently used method for analyzing potentially modifiable risk factors [52]. In old age, exposure to suicidal behavior is mediated by a higher prevalence of medical conditions, mental illness, difficulties in adapting to life transition events, lack of social support, and bereavement.

Physical Illness and Cognitive Impairment

Fässberg and collaborators, through a systematic review of the literature [60], analyzed the role of physical illness and functional disability concerning suicidal behavior in individuals aged 65 and over. From their analysis of 65 articles, the most consistent results showed that suicidal vulnerability has a significant association with different levels of functional impairment and certain physical conditions such as oncological diseases, neurological disorders, male genital disorders, arthritis/osteoarthritis, chronic and progressive lung disease (COPD), and liver disease.

Although somatic diseases and functional impairments increase the risk of suicide at every stage of life [29], the results’ strong heterogeneity makes the specific role of physical disease in this area uncertain.

In particular, differences in severity levels of the medical condition, history/number of hospital admissions, and medical visits are not clear [9], nor the presence of independent associations between severe physical illnesses and suicide [41, 168]. The diagnosis of dementia is an example of this debate: for some authors, it seems to contribute to the risk of suicide [51, 143], while for others it is not possible to find any evident association (e.g., [144]).

A recent study by Wang and collaborators [170] showed that, among a sample of older adults living in rural China, the severity and number of physical illnesses were related to death by suicide. Considering the high rates of suicide among older people in rural China [66], these authors suggest that the association between physical illness and suicide may depend on the relevance of specific cultural factors, such as dishonor – for the sick – in failing to fulfill its social role. This could be supported by the almost gender equality in suicide rates among older Chinese people, as if in some contexts risk factors such as physical illness may jeopardize the public role of individuals (due to the strong reference culture in terms of duties, expectations, beliefs) and be more influential than any individual vulnerability. In addition, older

Chinese people living in rural areas tend to have low incomes and poor access to care. In this case, physical illness could act as an additional stressor and accelerate the role of precipitating factors such as depressive symptoms, despair, or other mental illness.

In a study by Koo and associates [93], based on data from the Queensland Suicide Register, physical illness as a suicide risk factor becomes of primary importance in the most advanced age groups (from 85 years upward). Furthermore, in parallel decreases the role of psychiatric diseases, prevalent in the younger old [93].

Psychiatric Illness, Suicidal Ideation, and Personality Factors

Numerous studies, conducted in different countries such as Canada [86, 134], Sweden [167], Finland [154], the United States [30], New Zealand [9], the United Kingdom [70], and Hong Kong [24], have shown that mental illness is present, depending on the geographic area, between 77% and 97% of late-life suicide cases.

Affective disorders, with a prevalence of 54–87% of cases [31, 148], represent an almost 60 times greater risk of suicide in some areas of the planet [24]. Within this category, depression constitutes the strongest risk factor in old age [30, 138, 168], followed by minor depressive disorder and dysthymia [167].

Although depression occurs in only 8–16% of cases in the adult population, the presence of a depressive episode is sufficient to trigger the chain reaction that brings to a suicidal outcome [13]. The concept of “loss,” central to depression, seems to catalyze with great ease the feelings of fragility typical of old people, exacerbating feelings of despair, loss of interest and loneliness, somatic disorders, and cognitive deficits. This emotional experience leads the person to a “tunnel vision” such that suicide seems to be the only alternative. Especially in old age, recurrent thoughts of death and suicidal behavior can derive from the belief that life has lost its meaning and is no longer worth living. However, while suicide attempts tend to decrease significantly in frequency throughout life [42, 93], suicidal ideation appears to play a pivotal role in bringing ahead the suicide act in old age [24, 142, 165].

Suicidal ideation can occur in an active [162] or passive [14] form (death wishes) even in the absence of a depressive disorder, especially in the context of primary care [137]. In particular, suicidal ideation appears to be associated with several mental health conditions, such as anxiety disorders [14], somatoform disorders [172], disability [103], low family income [25], and socioeconomic inequalities [64].

In the context of primary care, screening for depression and assessment of suicidal ideation play a crucial role in saving an older person from suicide.

The greatest difficulty lies in discerning pathological thoughts and behaviors from normal reflections about death [145]. However, it must be considered that older people with mental disorders hardly turn to specialist services, finding instead in the family doctor a more intimate and accessible reference figure with whom to discuss their health [151]. The crucial role of primary care services is demonstrated by numerous studies reporting that about half of suicide decedents, in the month before death, came into contact with their primary care provider [3, 101] or had a previous hospitalization [109, 120].

The presence of schizophrenia [24], personality disorders, and mental retardation [70, 83] can also influence suicidal behavior. The study of personality traits and suicide is still poorly explored in old-age groups and that the association is more evident among young people [50, 119]. It is possible to hypothesize that individuals with anancastic or anxious traits, once exposed to stressful factors, may tend to exhaust their coping strategies quite easily, exposing themselves to the risk of suicide [28].

Substance abuse [149], even in the absence of other clinical disorders [167], appears to interact rapidly with other risk factors such as medical disease, and poor perception of control and depressed mood, amplifying the risk of suicide. This association of factors has been frequently reported among older people living in countries such as Russia, Ukraine, Belarus, the Baltic regions, and the old republics of the Soviet Union [91].

Psychosocial Factors: Adverse Life Events and Transitions

From a psychosocial perspective, older adults who face the loss of a spouse, the bereavement of a loved person, or living in a nursing home are at greater risk of wanting to end their life [40, 56, 92]. It is known that isolation and loneliness are among the most important predictors of late-life suicide [15, 19, 49, 104].

Poor social integration often implies distance from relatives, rare visits from friends, lack of confidence, and participation in religious services. These elements can become precipitants, especially if associated with low resilience, inadequate coping strategies [53, 157], or a natural tendency toward introversion, a condition that contributes to the loss of interest in new activities and refusal to ask for help [54, 156].

The lack of effective skills to deal with adverse life events also has repercussions on tolerability in managing transition processes, which characterize the aging phase. Low income and financial difficulties, relocations or transfers to nursing homes, and a job change to a minor role can increase the risk of suicide [75, 98, 142].

A recent Australian study, based on over 250,000 individuals over 45, has shown that the transition from employment to retirement, especially if pressured, is an important risk factor for suicide and negatively affects mental health [129]. Indeed, these changes can generate feelings of worthlessness and low self-esteem, supported by social representations of aging, which, too often, tend to regard this stage of life with contempt [115].

Protective Factors

Not much research has been dedicated to protective factors in old age [35]. Undoubtedly, the study of resilience in older people and related gender differences could bring out numerous insights into how to cope with losses, the propensity to ask for help and cultivate good interpersonal relationships, as well as flexibility and adaptability [18, 113].

To date, research has identified family and social support as the main protective factor: being married [69, 90, 129], having children [142, 166], being engaged in religious and spiritual activities [34, 62] or pursuing a hobby within an organization [142, 166], dating friends and relatives [31], all seem able to strengthen the sense of solidarity, satisfaction, and meaning toward one's life, increasing psychological well-being. To these elements are to be added adaptive coping strategies and healthy lifestyles [141], together with a good level of education and an advantageous economic situation [62].

Prevention of Late-Life Suicide

Suicide prevention in old age is a particularly challenging task. The main obstacle lies in the scarcity of studies in this specifically targeted group [5, 102], to which should probably be added reasons such as little attention to demographic differences, lack of a standard nomenclature, exclusion of at-risk individuals from clinical trials, and the generally modest professional training in suicidology among physicians [77]. For all these reasons, knowing in depth the characteristics of suicidal behavior in this particular segment of the population becomes crucial for planning and implementing effective prevention interventions.

First, the planning of interventions must analyze the social and cultural environment of reference to balance the relevance of risk and protection factors depending on the context [33, 175]. In countries like China [132] and India [130], the association between suicide and mental disorders is less evident than in countries like the United States, where depression is reported with a much stronger correlation [171].

The identification of risk and protective factors through epidemiological research has made it possible to enrich knowledge in this area, particularly about the psychological and cognitive mechanisms involved in suicidal behavior. However, it must be taken into account that the data on each risk factor comes from aggregate information, which is insufficient to determine with reliability the seriousness of a specific case [76]. To this awareness is to be added the multifactorial nature of the phenomenon, for which only the synergistic action of several factors contributes to the fatal outcome [175].

Although methodological shortcomings call for caution in interpreting study results, suicidology has developed in many countries worldwide, with a wide variety of promising, effective, and sustainable preventive approaches [175]. The main preventive interventions of suicide in old age are presented according to the nomenclature endorsed by the World Health Organization [175].

Universal Prevention Interventions

Universal prevention is aimed at entire populations and aims to reduce the incidence of suicidal behavior within nations or local communities.

This type of intervention aims to educate the population through the improvement of skills, information, and resources [96]. Also, it focuses on studying risk and protection factors on a large scale and developing guidelines for responsible media reporting on suicide [57].

To date, multilevel interventions and national strategies constitute the main prevention actions that include this goal. In particular, multilevel interventions act on the three levels of prevention, including four action plans valid for all age groups: (1) optimization of the diagnosis and treatment of depression; (2) media campaigns to reduce the stigma concerning depression and help-seeking; (3) training of gatekeepers; and (4) targeted interventions for high-risk groups. These interventions are defined geographically, and, since they are research-based, they differ from interventions foreseen within national programs for suicide prevention [26].

The guidelines for the formulation of national strategies, drawn up by the United Nations [158], identify multidisciplinary collaboration and continuous monitoring as key elements. In particular, they highlight the need to make suicide prevention a multisectoral priority, adaptable to the diversity of social and cultural contexts, by identifying best practices and an effective allocation of resources.

To date, national strategies recognize the importance of late-life suicide, promoting access to integrated mental health services and supporting older people and their carers [116, 117].

Community-based awareness programs are, among the multilevel interventions, those most used specifically for old-age people. Several studies, conducted by Oyama et al. [126–128], implemented this type of program in rural areas of Japan, where there were very high suicide rates. Specifically, the interventions included mental health workshops to raise awareness of depression and suicidal risk, annual depression screenings for all residents aged 65 and over, clinical interviews with a psychiatrist or general practitioner, and follow-up meetings with specialized nurses. The combination of group activities, psychoeducation, and self-assessment of depression was found to be effective in reducing suicide, especially in women.

Selective Prevention Interventions

Selective prevention interventions target seniors potentially at risk of suicide, such as those who have recently retired, suffered a bereavement, were recently discharged from hospital, or suffer from a chronic illness. At this level, three macro areas of action should be contemplated: (1) specific interventions for vulnerable groups, (2) implementation of helpline services, and (3) community-based gatekeeper programs [175].

1. Interventions for Vulnerable Groups

Lack of clinical expertise in diagnosing depression and detecting suicidal risk, as well as poor training in suicidology, in general, constitutes the main obstacle to the prevention of suicide in old age at the selective/indicated level [77].

Particularly in the context of primary care, physicians should probe for the presence of depressive symptoms in older people with memory problems, severe physical conditions, functional deficits, or sleep problems. Emphasis should be on the presence, severity, and duration of mental disorders without loosening vigilance in patients who do not present suicidal behavior or ideation [118]. In addition, physicians should be trained to manage emotionally altered conditions even in emergency settings and provide ongoing care for the assessment and support of at-risk older people, fostering interdisciplinary approaches to care [107].

In this sense, selective interventions have – as their main objective – the improvement in psychiatric treatment strategies (e.g., drug compliance), the increase of awareness about important life events for older adults and alcohol abuse, and a specific focus on different medical conditions [57].

In addition, physicians need to be provided with systematic screening tools to assess depressive symptoms, behavior, and suicidal ideation in older adults who fall into risk categories. The Patient Health Questionnaire (PHQ) is one of the most widely used measures for detecting depression in the context of primary care [152]. It is a structured screening with a series of items that investigate the frequency of the main depressive symptoms (absence of pleasure and depressed mood), physiological (lack of sleep or appetite), and the presence of thoughts of death. Numerous studies have confirmed the predictive value and usefulness of PHQ, particularly for suicidal ideation [85, 97, 133].

Also, the use of semi-structured interviews such as the Geriatric Depression Scale (GDS) [180] and the Geriatric Suicide Ideation Scale (GSIS) [79], which include the analysis of related symptoms such as hopelessness, worthlessness, and meaninglessness toward life, is a useful tool for identifying potential older adult suicidal people [78, 79].

2. Helplines

Although older adults do not preferentially use helplines [2], this service has proved useful to guarantee support for people in crisis [111], integrate or provide short psychotherapy [139], and increase treatment adherence and motivation in individuals with histories of suicidal behavior [20].

In the specific case of older adults, helplines could be an additional source of community-based support to strengthen the sense of social connection and decrease feelings of isolation and loneliness [115].

In Italy, a team of researchers led by De Leo et al. [36, 38] implemented a telephone support program to reduce the risk of suicide in individuals aged 65 and over. Approximately 20,000 seniors were selected based on a standardized screening, which included the presence of somatic and/or mental disorders, physical and/or emotional isolation, and a range of known risk factors for suicide. The intervention, called TeleHelp & TeleCheck, was structured to guarantee a 24-hour emergency telephone service and a biweekly support service. Even after a long time since its implementation (the service is still running), it is believed that this program has contributed significantly to the prevention of suicide in old individuals, especially among women [37].

Another intervention focused on using the telephone line was proposed by Morrow-Howell et al. [112], who devised a telephone support service within a suicide prevention hotline. After 4 months, the Link-Plus program reported a significant reduction in depressive symptoms.

Two years later, Fiske and Arbore [61] initiated a community-based geriatric care program for suicidal seniors. The intervention included two action plans: the Geriatric Outreach had the task of providing telephone consultations and home visits. At the same time, The Friendship Line guaranteed emotional support, information on local services for older adults, and prompt intervention in the event of a suicidal crisis. At the 1-year follow-up, the study reported significant results regarding the reduction of feelings of hopelessness.

3. Gatekeeping and Peer Support

Another important goal of selective interventions is the training and education of gatekeepers, who can identify seniors at risk of suicide within the community. Strengthening the skills of mental health and primary care services in social workers, educators, and law enforcement agencies can prove to be very useful in recognizing and treating the most vulnerable people [175].

Older adults, in particular, are likely to turn to primary care facilities rather than specialist services [31]. In this sense, gatekeeper's role could be assigned within informal networks, such as senior centers and peer support groups, as well as in wider community networks such as banks, utilities, pharmacists, and postmen [28].

The focus of these interventions should encourage the autonomy and independence of the subject, the importance of healthy aging and social integration [120] by facilitating the transition from working life to retirement [129], and favoring proactive coping styles [169].

Van Orden [163] and colleagues have devised an innovative program to prevent the development of suicidal ideas among seniors at risk, combining the gatekeeper's function and the action of peer support. The Senior Connection is a community-based service. Older adults from primary care services, who report poor social integration or perceive themselves as a burden to others, are referred. The goal of the program is to increase the sense of social connection through companionship and peer interactions. In particular, each participant is assigned an older tutor, who can guide the integration process.

In these terms, the collaborative network between primary care providers, gatekeepers, and specialist services could help to significantly reduce the risk of suicide among older people [63].

Indicated Prevention Interventions

Indicated prevention plans focus on individuals who exhibit high risk of suicide behaviors, such as acute suicidal ideation or being a survivor of a suicide attempt.

Particularly in old age, such interventions are preferentially designed on collaborative care models [35, 76, 121] that connect primary care providers with mental health-care specialists [125]. These interventions involve doctors, nurses, social workers, and psychologists [136] and aim to optimize the processes of suicide risk assessment and the reduction of depression and suicidal ideation [89, 125].

In general, these interventions should guarantee decisive and immediate help through social and community resources, facilitating communication with older patients through the training of professionals and gatekeepers in the field [4]. They should implement home follow-up or by telephone [37] and develop practical guidelines, stimulating the use of systematized registers to identify better people who have attempted suicide [57]. Currently, psychosocial and clinical interventions are the main action plans for suicide prevention in old age at this level.

1. Psychosocial Interventions

IMPACT [160, 161] and PROSPECT [4, 16] are two treatment strategies that, through a randomized controlled study, examined the effect of the program on older depressed patients from primary care settings. In both studies, the control group received the usual care. In contrast, the experimental group received support for depression from health professionals, a brief psychotherapy treatment (interpersonal or behavioral), monitoring of depressive symptoms and drug side effects, and follow-up actions. After 12 months (IMPACT) and 24 months (PROSPECT), the studies reported a significant decrease in depression, suicidal ideation, and functional deterioration. In particular, the development of therapeutic alliance, personalized treatment plan following the patient, proactive follow-up system (monthly or biweekly depending on the severity of the risk), were the main elements capable of promoting psychophysical improvement and a greater sense of confidence and self-efficacy.

Another type of innovative psychosocial intervention has been aimed at old people at high risk of suicide, intercepted in emergency wards, to reduce or contain future suicidal crises [153]. Since these patients tend not to follow the mental health treatment recommended in the clinic consistently, the Safety Planning Intervention (SPI) is proposed as a short first aid intervention useful for structuring a personal safety plan. In particular, it involves the development of a written list of coping strategies and formal and informal assistance networks capable of implementing immediate responses to crises.

Sirey and associates [150] analyzed the efficacy of a short psychosocial intervention designed to incentivize mental health treatment initiation among older people with depressive symptoms who receive a meal-at-home service in the United States. *Open Door*, so-called, included five phases of intervention and motivational interviews to stimulate the request for help, through in-person and telephone interviews. Compared to the control condition referred to the service, almost one-third of the subjects (27%) who benefited from the project reported a significant decrease in suicidal ideation [150].

While the studies cited so far focus on risk predictors, Lapierre et al. [95] implemented an intervention to strengthen protective factors such as resilience. Based on a cognitive-behavioral approach, the program consisted of a cycle of seminars and small group activities for older people who could not tolerate the transition to retirement. After a 6-month follow-up, about 80% of the experimental group subjects reported the absence of suicidal ideation, depression, and psychological distress in favor of an improvement in the sense of hope and meaning toward life, flexibility, and serenity.

2. Clinical Interventions

In the literature, it is known that some pharmacological treatments can limit suicidal behavior, for example, through the use of drugs such as lithium [8], clozapine [110], antipsychotics [71], and antidepressants [7]. Currently, no studies based on drug and/or psychotherapy therapy have yet shown significant efficacy in decreasing the risk of suicide in older adults [77]. However, Scogin et al. [146] found that if involved in the choice of intervention, older adults prefer psychological or combined treatment, rather than just pharmacological.

Interpersonal psychotherapy (IPT), conceived by Klerman et al. [89] in the 1970s, is a time-limited form of treatment that focuses on the patient's present relationships. This psychotherapy's purpose lies in identifying and transforming the maladaptive personal context, focusing on the problems inherent in pain, conflicts and role transitions, and interpersonal deficits. Due to these peculiarities, this psychotherapeutic treatment appears to be useful in reducing suicidal ideation in old-age subjects.

Heisel and associates [81, 82], on the other hand, used interpersonal psychotherapy to strengthen protective factors in adults over the age of 60 at high risk of suicide in order to improve social support and satisfaction of interpersonal needs. The intervention, which lasted 4 months, offered weekly outpatient psychotherapy sessions, with the possibility of continuing treatment after the scheduled sessions. Additionally, participants were encouraged to improve their social connections and develop meaningful post-therapy relationships and activities. The study results showed a significant decrease in suicidal ideation and depressive symptoms and an increase in social adaptation and enjoyment of company activities.

Szanto and collaborators [155] analyzed the results from three studies for the treatment of depression in old age, based on the administration of nortriptyline and weekly IPT, paroxetine and weekly IPT, and nortriptyline and paroxetine, respectively. After 3 months of treatment, the decrease in suicidal ideation had tripled: at the beginning, only 22.5% of subjects denied the presence of suicidal ideation, while at the end of the trial, the percentage reached 81.6%.

Reminiscence therapy is a rehabilitation intervention designed specifically for old age, which uses a narrative approach to enhance remote memory skills, integrating past memories with current ones. The treatment exploits the natural propensity of older people to recall their past, favoring the processing of memories, in order to better interpret and live daily reality, limit isolation, strengthen self-esteem, and personal identity. A study of 256 nursing home seniors without a diagnosis of depression showed that the group undergoing reminiscence therapy reported lower

scores for depressive symptoms and hopelessness, even after the 1-year follow-up. These results lead us to hypothesize that this therapy may be useful for regulating mood alterations in seniors living in institutionalized settings [68].

Problem adaptation therapy (PATH), designed to reduce depression through the development of problem-solving skills, and supportive therapy for cognitively impaired older adults (ST-CI), based on the Rogersian approach of empathic listening, both showed a significant reduction of suicidal ideation after 3 months of treatment [88].

Other psychotherapeutic approaches that are effective among young adults, such as cognitive therapy [17], dialectical behavior therapy (DBT; [100]), and problem-solving therapy (PST; [108]), may be valid in decreasing suicidal behavior among older people but still need to be tested systematically.

Gender Differences in Late-Life Suicide Intervention

Globally, older men tend to die by suicide up to 7–8 times more frequently than women of the same age [114], especially in late old age. These data must be taken into account in planning preventive interventions aimed at this subgroup of the population.

The main gender differences in suicidal behavior among older adults relate to a higher tendency in men to carry out a suicide attempt with a fatal outcome [12], while in women to attempt suicide [72], and the use of more violent means, such as firearms and hanging, among the male population. Although women appear more vulnerable to depressive disorders [1], they are more resilient and more likely to seek help from mental health services [48]. In contrast, men, especially when very old [44], appear less prone to adaptation to stressful life changes and are less likely to undertake a therapeutic path [164].

These data would explain why older women, generally more disposed to dialogue and to receive emotional support, seem to benefit more often from the intervention programs implemented so far [37, 38, 128]. On the other hand, men seem to offer better results with more practical and problem-solving approaches [67, 128].

Finally, it must be considered that the very doctors may not refer older men to collaborative assistance programs, also by atypical manifestations of depression in the male population, making the choice of intervention more difficult [46, 84]. Another traditional obstacle is represented by the ageist perspectives of aging, with their heavy responsibility in authorizing lax approaches to the suicidal issues of older patients, implying the inevitability of the exit of “too old” people, no longer “useful” to societal dynamics [45].

New Frontiers for the Prevention of Suicide in Old Age

Research and suicide prevention activities in old age are still a little explored area [96]. In general, it would be advisable to carry out comparative studies on prevention interventions concerning different age groups and according to gender, selecting

similar outcome variables to favor the comparison between different types of intervention.

Since epidemiological data provide information on the cause, mode of death, and demographic characteristics, it would be highly suggestible to establish a national database that collects in-depth information on suicidal behavior to expand surveillance and introduce targeted preventive activities [76].

Furthermore, it would be useful to increase the volume of research on protective factors such as positive aging, adaptability, and resilience [96]; for example, through psychological autopsy studies, the association between protective factors and suicidal behavior could be analyzed in a representative sample of older adults in different rural and urban areas.

It is essential to involve clinical psychologists, doctors, and family members toward a cultural change to the reference ideas on mental illness and aging, promoting the recognition of the value of older people and social inclusion [77]; government policies must also act in this process, to improve retirement programs and provide better access to mental health [35].

At the level of universal prevention, it is necessary to favor routine screening for depression and implement preventive programs for the restriction of means, designed specifically for old-age people [96]. Furthermore, it would be advisable to include, within the multilevel interventions, interventions aimed at older adults. The European Alliance against Depression has indeed shown that it is possible to implement basic but important elements, in different cultural and demographic contexts, through a standardized procedure [74].

Particularly for older people, it is essential to reduce the generational stigma for help-seeking behavior and the labeling of depression, often supported by ageist perspectives [45, 96]. In this sense, one of the main priorities lies in educating doctors on suicidology, inducing them to consider multiple risk factors of different severity [84], and to verify the impact of such education in the medical field concerning the suicide in old age [46, 96].

Furthermore, the training of community guardians [106] and the study of the quality of life of seniors living in institutionalized contexts, such as nursing homes, are essential to reach the people at risk of suicide [96].

The development of telecommunication technologies, based on the telephone, videoconferencing, and web, can be useful for offering support to frail elderly people, encouraging help-seeking behavior, screening and assessment of suicidal risk, and the dissemination of useful information to identify territorial, appropriate resources [94, 99, 124].

Prevention interventions at the indicated level should encourage the frequency of visits and monitoring of older people at risk within primary care facilities, expanding the range of risk factors to be considered in this particular age group [96].

Some innovative aspects concern the implementation of studies on substance abuse and impulsiveness regarding suicidal behavior in later life and the possibility of involving relatives and key caregivers within the treatment process [96].

Finally, future research should focus on devising new psychosocial interventions, which appear to be a promising method for reducing late-life suicide. In fact, in this

specific population group, pharmacological treatment is limited due to the often moderate effects of the treatment, drug–drug interactions, and greater vulnerability to side effects [47]. On the other hand, clinical interventions must focus on treating older people who have suicidal characteristics even in the absence of depression and explore potentially effective therapies, including family therapy [140].

Conclusions

Suicide in old age brings out the difficulties of facing a composite phenomenon such as aging, which involves researchers, professionals, and politicians in their role as experts and future users. In modern culture, collective experiences tend to relegate older individuals to marginal and stereotyped contexts: the grandfather, the pensioner, the sick, and, in some cases, the inept.

However, looking at aging from an evolutionary perspective, it is possible to consider entry into old age as a physiological process that increases the entropy of a system. Contrary to the ageist visions of aging, the older adult can be thought of as an even more complex and diversified individual, capable of developing particular adaptive capacities, precisely by their age.

Thanks to life experiences and the less hectic pace of their present lives, seniors have more time to reflect, process, and transform ideas and behavior patterns adopted in life, developing powerful wisdom and resilience. In this sense, the guiding principle of preventive interventions lies not only in the observation that suicide in old age is preventable but above all that it is a battle worth fighting.

risk for suicide is often more difficult for clinicians to detect in older adults than in younger adults. While relatively little attention is spent on educating clinicians about suicide in older adults (65 years old and over), it is a significant problem that warrants increased and ongoing attention from educators, healthcare providers, researchers, and society at large. The risk factors and the expression of suicidality are different for older adults when compared to their middle-aged counterparts. When evaluating for suicide risk, it is important to consider age, gender, gender identity, ethnicity, occupation, and socioeconomic status. However, older adults have additional risk factors that may be missed such as changes in health status, loss of a spouse, social isolation, and lack of purpose or reasons for living. Older adults from different ethnic backgrounds may also have different risk and protective factors based on their experiences, religious beliefs, and cultural customs. Protective factors also vary for each subgroup of the population. Identification of older adults at risk and their protective factors is important for early intervention and treatment. This chapter will provide a description of the complex nature of suicide and aging and elaborate on the risk and protective factors. The development and implementation of evidence-informed strategies that are aimed at suicide prevention can promote a reduction in the epidemic of late-life suicide.

Introduction/Purpose

Suicide is a public health concern of the global dimension because it results in devastating effects, not only on the deceased person's family, but on community morale as well [20, 23]. Suicide is a leading cause of death in the United States, with certain age groups being at higher risk, including adolescents and older adults [31]. Risk factors in the general population include psychiatric disorders, genetics, substance use, gender, marital status, physical illness/ailments, employment, status, social support, and socioeconomic status [31]. In general, suicide rates rise with age, with older adults over the age of 60 years at greatest risk [7, 35].

Advances in rehabilitative medicine and healthcare coverage are increasing life expectancy globally [25]. Following this trend, the overall American population is progressively becoming living longer in late life [29]. Because of the baby boomer generation, the older adult segment (age 65 and older) is the fastest-growing stage subgroup of the population [9]. Despite the increasing numbers of older adults who die by suicide, the bulk of media attention continues to focus on suicide deaths by youth, adolescents, and young adults [11]. This attention bias implies that death by suicide by this age group is somehow less problematic because older adults have lived the majority of their lives. Noteworthy is that other cultures, those that are collectivistic and eastern, may not hold this bias due to their cultural norms regarding the treatment of older adults when compared to western cultures. It is not unusual for older adults to go without adequate care for mental health issues due to stigma,

misinformation, and false beliefs about aging and instead be prescribed psychotropic medication that treats some symptoms of distress but fails to address underlying mental health concerns [34]. The lack of awareness about the mental health and aging can result in some clinicians believing that older adults have outgrown any earlier manifestations of psychopathology. Yet, older adults and individuals born post-World War II and Holocaust survivors are at a higher risk for suicide when compared to other birth cohorts due to their war experience stressors [2, 9]. It is likely that generational trauma from war and general community stress influenced the psychosocial development of these individuals as children and predisposed them to respond to stress by seeking escape as a coping mechanism.

This chapter will provide an overview of suicide rates in the United States and compare younger and older adults. The focus of this chapter is on risk and protective factors for older adults, with implications for providers and family members to help reduce death by suicide by older adults. Factors such as gender, race, ethnicity, education, socioeconomic status, and health are considered as well as access to means. Additionally, the prevalence of psychiatric illness and physical illness among older adults is considered. Finally, the screening, assessment, and treatment of suicide is reviewed in order to help mental health professionals monitor and increase the well-being of older adults.

General Suicide Rates in the United States

Rates of suicide continue to increase despite policy and clinical initiatives that target reducing suicide rates in the United States [28]. Indeed, numerous research studies are routinely conducted to examine risk and protective factors, conceptualization models, and treatment approaches. Yet, suicide rates continue to increase across gender, racial, and ethnic groups [36]. Some examples of factors influencing these rates could be minority stress, cultural perceptions of mental health treatment, negative interactions with healthcare professionals, or a combination of these and other factors. A 33% increase has been reported in deaths by suicide from 1999 to 2017, and it continues to remain the tenth leading cause of death in the United States [42].

Suicide in Older Adults

As a whole, suicidal ideation manifests differently across age groups, with differences in both risk factors and method of death [27]. There is some homogeneity across age groups (children, adolescents, adults, and older adults) with regard to risk factors for suicide, including psychiatric illnesses, access to firearms, impulsivity, poor coping skills, and gender identity [4, 28]. Unlike other age cohorts, research shows that children and adolescent suicide attempts are not typically driven by a desire to end their lives but rather a cry for help [4]. This implies problems with communicating distress and securing appropriate help. Age-specific risk factors for children and adolescents also include family history of suicidal behaviors, attempts, and deaths; aggressive or disruptive behavior, exposure to violence (i.e., physical

and sexual abuse); rejection or neglect; and bullying [4]. Interestingly, this finding suggests that other age cohorts may be better able to express their distress or have made the decision to covertly end their lives. A combination of stigma and social isolation among older adults may contribute to a larger number of deaths by suicide without warning signs and with greater lethality. Young adult and older adult suicidal risk factors are similar and include educational level, type of occupation, as well as problems related to unemployment, marital status, socioeconomic status, presence of mental illness that is amplified by a coexisting personality disorder, and substance use [28]. A noteworthy point is that these factors can and often do co-occur with one another, further increasing the level of risk. Of great concern is that older adults consistently use more lethal means, particularly firearms, for dying by suicide and are often more isolated leaving them with less opportunities for rescue or intervention by an outside party, particularly when compared to younger cohorts [5, 10, 19].

As previously mentioned, suicidal ideation and behavior among older American adults have become a serious public health problem [24]. Because they are the fastest-growing age group, the number of older people who decide to die by suicide will continue to increase [19]. It is estimated that for every four older adults who make a suicide attempt, there is one death by suicide. This is greater than other age groups, where estimates show approximately 25 attempts result in one death by suicide in younger cohorts [35]. The death by suicide rate is most likely influenced by access to and use of lethal means that is coupled with a lower possibility of being rescued. Young adults and adolescents may have more opportunities for a family member to check in on them or a roommate who is able to interrupt an attempt.

Older adults make up about 15.2% of the US population [1]. Yet, suicide in later life often remains overlooked and is a major concern, particularly because of the high prevalence and fewer warning signs [3, 11, 19, 38]. This category of adults represents the greatest risk for suicide than any other age-group and accounts for higher rates of death by suicide when compared to younger adults (Conwell et al. 2002), resulting in approximately 18% of all suicide deaths [19]. Higher rates of death by suicide could be attributed to social isolation, stigma about mental health (self-judgment for experiencing distress), or hopelessness related to physiological health. Considering that older adults make up 18% of suicides in conjunction with the fact that 75% of older adult attempters do not die by suicide, one can imagine how much higher suicide rates would be if more attempters died by suicide. Thus, there is a need to continue to stop attempts as well as prevent older adults from getting to a level of distress where they consider attempting suicide to be their best option.

Suicide and Gender Identity

Suicide risk and behavior are influenced by sex [23]. Due to stigma surrounding nonbinary genders in this generation, literature on nonbinary older adult suicide is sparse. Overall, women attempt suicide at a higher rate than men; however, men tend to make more serious attempts by using more lethal methods [23]. Additionally, women are more likely to seek out social support when distressed, whereas men are

more likely to isolate [6]. This decreases the possibility of being stopped when attempting to die by suicide. Another factor that increases the risk for men is the method of suicide death. Access to and the use of firearms was associated with men's attempts and the risk increases with age [11]. Possession of firearms by older adults may be due to cohort effects or concerns about safety and protecting oneself. Suicide risk is also affected by marital status in both men and women where widowed men and women's suicide rates are 3.3 times higher than married men and women [23]. In women, those who are divorced or separated accounted for higher suicide rates compared to married women [23]. Relationship satisfaction has been found to be more indicative of suicide risk than marital status as a whole. Married women who are unsatisfied with intimacy are more likely to endorse suicidal ideation [6]. It appears that women require strong emotional support and intimate connection for a relationship to be protective. Suicide rates have been on the rise among both older men and women [24]. The highest risk for death by suicide is among older White men [13]. It is worth noting that suicide rates among older adults in some cultures are relatively low when compared to younger cohorts, particularly for indigenous groups [35].

Suicide, Race, and Ethnicity

Suicide rates differ across the population, particularly with regard to ethnic and demographic groups as well as geographic regions [20]. In general, African Americans attempt and die by suicide at younger ages [20]. When looking at suicide rates and race in older adults, Asians and Whites report the highest rates of suicidal ideation whereas African Americans have the lowest reported rates of ideation [23]. However, the highest suicide rates remain among White, particularly non-Hispanic White men over the age of 85 years [24]. An important consideration is the effect of minority stress on day-to-day functioning, willingness to seek treatment, access to treatment, and social coping resources.

Suicide and Education/Occupation/Socioeconomic Status

In general, low socioeconomic status (SES) and less educated older adults are often at greater risk for death by suicide [15]. These individuals may have had negative prior interactions with healthcare providers and insufficient access to services or financial resources to afford care, or do not consider the care to be worth the cost and effort to obtain. A relationship between SES and suicide has also been found to be true for older adults. Older adults that attempt or die by suicide were found to have completed less education than their younger cohorts, most likely due to a lack of resources or difficulty obtaining an education [38]. Low SES may be indicative of low education, mental illness, or even familial factors [15]. Links between suicide in late life and low SES could be explained by the adverse effects that low SES has on older adults when compared to younger adults [31]. Examples include job

discrimination, low social security benefits, physical limitations that prohibit the ability to perform some job, and feelings of worthlessness stemming from an inability to work. For older adults who do not intentionally retire when they are financially able, it is no surprise that unemployment rates among older adults are high [38]. It is likely that after retiring some older adults are unable to exist on social security alone without financial assistance from their families. They may then be discriminated against by potential employers because of their age and potential age-related limitations. Unemployment or lack of a sufficient and stable income may contribute to higher suicide rates among older adults [38]. It is possible that this could be a stand-alone risk factor, or it may be a factor that contributes to feelings of hopelessness, worthless, and despair.

Risk Factors

Suicidal ideation is a major risk factor for suicide that elevates the potential for more serious suicidal behavior [27]. Thinking about dying by suicide may desensitize individuals to these thoughts and make suicide seem like a reasonable solution to an often temporary or solvable problem. However, establishing and understanding the cause of such a multifaceted, subjective, and complex behavior are a laborious task [11]. According to the stress-diathesis model of suicide, vulnerability is a predisposition to suicide, especially in conjunction with individual risk factors [7]. Some significant risk factors include a history of suicide attempts, family history of suicide, isolation, and substance use. Risk factors can vary by cohort and age group but often including individual disposition, relationship status, and community involvement [26]. These risk factors can intersect to have compounding effects as well. For example, a 70-year-old man, experiencing anhedonia, with no living family, who is not involved in his community may have a higher level of risk than a 70-year-old man who experiences anhedonia, lives with his son, and plays chess with his friends at the senior center. The following risk factors are not exclusive to older adults but are associated with older adults at risk for suicide: psychiatric illness, physical health, social connectedness and support, and functional capacity [11]. As previously mentioned, these can combine in any number of ways to affect an individual's global level of functioning and influence their level of risk.

Psychiatric Illness

Psychiatric illness is the most potent risk factor for suicide in older adults [11]. It is estimated that approximately 85–90% of older adults who died by suicide had a major psychiatric illness or diagnoses at the time of their death [39]. It is likely that some older adults underreport experiencing psychiatric symptoms (e.g., feeling of depression) prior to dying by suicide and that many clinicians are not able to detect increased suicide risk because of inadequate training or time constraints. The prevalence of major depressive disorders is high in older adults and is a key risk

factor for suicide [24]. The majority of older adults who die by suicide carried a diagnosis of depression [32]. Whether their distress was communicated to those around prior to their death is unknown. Some older adults who share their distress with their family members may find them minimizing their experiences because they do not know how to respond and provide assistance. Healthcare clinicians in all settings may rationalize the distress of older adults as normative to the aging process. In long-term care settings, it is not uncommon for older adults to state that they wish they could go to sleep and not wake up. At minimum, healthcare workers should consider this a cry for help, and mental healthcare should be provided to address the feelings that life is no longer worth living.

Psychotic illnesses, anxiety disorders, and substance use disorders are not the primary factors driving older adult suicide when compared to younger adults (Conwell et al. 2002). This further supports the need to treat depressive symptoms in older adults. Dementia represents the highest risk factor among neurocognitive disorders for suicide among the older adults [7]. Symptoms of a neurocognitive disorder can sometimes mask symptoms of depression. Consider that confusion or inability to carry out activities of daily living could mask symptoms of anhedonia. Cognitive symptoms of depression are often intertwined with those of a neurocognitive disorder. Older individuals are less likely to disclose suicidal ideation and more likely to present with fewer mood symptoms but more fatigue, concentration difficulties, and memory issues, making detection of suicide risk and a diagnosis more challenging [38].

Physical Health

Physical conditions and impairments increase with age. There is a strong association between physical illness and suicidal ideation and behavior among older adults [7]. Some older adults live with a physical illness and experience feelings of hopelessness. Physical illness often decreases independence and autonomy, which in turn erodes self-esteem while resulting in higher levels of stress [38]. This stress could be momentary, or it could result in feeling like a burden to both family and close friends. As the number of physical impairments increases, the risk for suicide escalates [11]. Suicidal ideation emerges as a result of frustration, pain, and loss of dignity and pleasure in life [7]. These older adults likely begin to look for an escape and start to rationalize that they have lived enough already. Subsequently, as the number of diagnosed illnesses increases, so does the risk of suicide [39].

Other considerations related to physical health are pain and physical debilitating diseases. Pain is a significant risk factor for men, elevating the likelihood of thoughts of self-harm and suicide [39]. It is likely that escapism is a factor, as well as self-judgment for not being able to overcome the pain. In general, chronic pain often doubles the chance of death by suicide [24]. On the other hand, some physical diseases are significant, stressful life events and not gender specific [7]. Specific diseases, such as cancer, heart disease, stroke, and COPD, are often associated with death by suicide [7].

Social Connectedness and Support

As individuals age, they experience physical changes and life events that are common but can still precipitate suicidal thinking and behaviors. These include reduced social status and financial problems (particularly debt) [22, 24]. As previously mentioned, health issues in late life are often associated with suicide. However, loss, loneliness, ruptured relationships, and interpersonal conflict are also common risk factors in late life [11, 39]. The intersection of physical health issues and a lack of social support to cope with these stressors contribute to an increased risk of death by suicide. When considering social connectedness and suicide in late life, the Interpersonal Theory of Suicide by Joiner and colleagues suggests that losing a sense of belonging and perceived burdensomeness are two causes for suicidal thinking [41]. Decreased belonging and increased feelings of burdensomeness may combine with isolation (e.g., family living far away, friends passing away) and result in loneliness. The feeling of being isolated coupled with social problem-solving deficits, such as the inability to resolve conflict, also increases suicide risk [7]. Suicide may present as the more desirable option rather than confronting difficult relationship dynamics.

The scientific literature additionally supports the notion that older adults who died by suicide were less likely to have a strong social support network due to being single, not having children, and not being involved in religious or spiritual practices [7]. Further, existing family may live far away, or it may be culturally normative for their family of origin to not value older adults. Physical health issues may hinder older adults from engaging in social groups or attending religious meetings. In addition, clustered stressful events often proceed suicidal attempts and deaths in the weeks and months prior [9]. Again, physical illness and loss are common stressors among older adults. However, loss, loneliness, and isolation that is coupled with physical illness increase the risk for suicide [9]. Significant losses can include as losing a partner or friends, losing a familiar living situation, and losing self-worth due to adjustment issues [24]. These individuals may then be unable to grieve or access coping resources (social support, mental health services, exercise) and see suicide as a reasonable option to cope with a difficult situation.

Functional Capacity

Another risk factor in older adult suicide attempts and deaths is a functional decline [22]. Consideration should be given to cognitive functioning, decision-making, and deficits in activities of daily living. Functional capacity deficits have been linked to increased suicide risk in older adulthood [39]. These deficits may act as a catalyst for hopelessness or mask symptoms of depression. Previous literature had indicated that impaired decision-making was related to poor impulsivity control and acting on suicidal ideation [7]. However, it is now suggested that impaired decision-making may also be linked to a lack of capacity or impaired ability to access and scrutinize past experiences and their possible consequences [7, 11]. Deficits in cognitive

inhibition indicate older adult's vulnerability to suicidal thoughts and, subsequently, death [7]. Further, a failure to control intrusive ideas and thoughts due to decreased executive control and cognitive inhibition can lead to triggering thoughts and suicidal behaviors [7]. Intrusive thoughts and impaired decision-making make for unstable mental health and can lead to suicidal behaviors.

Access to Means

Relative to their younger counterparts, older adults are more likely to use highly lethal methods, offer fewer warning signs, and engage in self-destructive behaviors [10]. Additionally, cohort effects can be observed. Owning a gun may be considered more culturally normative by older adults than younger adults. It is estimated that over 70% of older adults use a firearm to die by suicide [10]. With increased social isolation and fewer social connections, older adults who engage in suicidal behaviors are less likely to be found in time to thwart their attempt [9]. The use of lethal means would likely make it hard to save a suicide attempter who had a self-inflicted mortal wound.

The literature suggests that providers who are trained in lethal means safety are more likely to assess for access to guns and ammunition and engage in lethal means restriction with patients, their families, and close friends [30]. Therefore, one barrier to protecting patients with access to lethal means is provider competence. A study on geriatric care providers found that just one-third of providers assessed for suicidal ideation. When a patient made comments involving hopelessness and suicide, providers who had received training on assessment and lethal means counseling were less reluctant to assess for risk and access to lethal means [30, 33]. It seems that there is a domino effect where providers fail clients because their formal education failed to provide adequate training. To target this training deficit, the Counseling on Access to Lethal Means (CALM) training protocol was developed. The educational program describes warning signs and prevalence, types of lethal means (with an emphasis on firearms), and examples of reducing lethal means access [33]. Health providers who received the CALM training reported significant increases in assessment confidence, knowledge, and behavioral change (administering more assessment) from baseline to 3-month follow-up [33]. Having a healthcare provider who understands how to assess for ideation and lethal means could be a strong protective factor for keeping older adults who are experiencing suicidal ideation safer.

Protective Factors

Suicide becomes an escape for older adults who lack a positive outlook on life, feel useless or like a burden to others, and lack social connectedness [14]. Depressed mood is often shrugged off by family members who consider it normative aging. However, feelings of burdensomeness and social isolation are a dangerous combination. Adding invalidation from loved ones creates an environment primed for increasing suicide risk. Therefore, protective factors should be assessed and used in

treatment planning to offset the risk factors that are present for many older adults. In general, protective factors have not been studied as much as risk factors [26]. Understanding the role of protective factors could help prevent future deaths by suicide. Protective factors convey resiliency and include both societal and psychosocial conditions as well as behaviors that reduce suicidal behavior [14]. Protective factors sometimes appear in the absence of a known risk factor. For example, Heisel [22] suggested that lacking mental health illnesses, physical ailments, and introversion decreased the risk of suicide to a degree. Some people are simply less likely than others to be suicidal because of genetics, personality, environmental factors, or luck. Other protective factors include engaging in positive health behaviors, such as minimal alcohol use and regular doctor's appointments [22]. Similarly, the likelihood of engaging in these protective health behaviors could be a result of coping styles, upbringing, or some unknown variables. Other protective factors include personality traits, family connection, and involvement in communities that have the potential to prevent or mitigate suicidal thoughts, behaviors, and deaths [26]. Examples of protective communities are 12-step groups, religious organizations, and work environments. Other protective factors include religious beliefs, fear of disapproval, legacy, and obligations [3]. Even when considering death by suicide, individuals still are struck by a desire to not disappoint their God or harm their loved ones.

Strong social support can serve as a source of protection from late-life stressors, possibly protecting older adults from death by suicide [7]. This is true of many age groups; however, arguably, older adults typically have fewer built-in social interactions in their day-to-day lives. Consider retired older adults who are not involved in clubs or activities and rarely leave their homes. In particular, strong feelings of social connectedness and family involvement with significant others, children, and grandchildren can be potent social protective factors [26]. In addition to providing valuable social support, these connections can reinforce a sense of belongingness, purposefulness, and legacy. Further, religious beliefs and spirituality strengthen as a function of age. Because most religions typically do not condone suicide, participation in a religious organization provides both social and spiritual value to older adults [27]. Faith can provide comfort about what happens after death can instill a sense of hope. Overall, social connectedness may be an especially important factor to consider when developing treatment plans to address the risk for late-life suicide [11].

Screening/Assessment, Prevention, and Treatment Strategies for Suicide in Older Adults

Older adults, white men, in particular, are at the greatest risk for death by suicide [16]. Given the greater number of risk factors that adults face as they age (i.e., loss, adjustment issues, changes in health status, isolation, etc.), screening and assessing for suicide is critical [32]. Older adults may not disclose suicidal ideation to providers due to cultural norms, stigma, or lack of trust. Providers must screen for mental health problems during regular checkups. With so many individual factors influencing reporting style and clinical presentations, it can be difficult to identify

at-risk individuals in time to intervene. To develop more effective treatment approaches, it is important to study the etiology of risk factors [37]. The overall goal of suicide research is to prevent death by suicide [37]. Knowing the etiology and presence of risk factors can help providers know what to look for when working with older adults, elements to include in a treatment plan, and when to recommend more intensive care.

Screening and Assessment

It is important to screen and assess for suicidal ideation when risk factors are recognized, particularly for older adults [32]. As previously stated, many may be reluctant to volunteer information. Therefore, it is up to medical providers to recognize warning signs. However, due to the high prevalence of suicide and the few warning signs that older adults provide, a broad screen may be an important addition to routine medical checkup [32]. In this scenario, older adults could answer honestly without the pressure of a physician asking them directly. Additionally, the wording on some screeners may be less intimidating than being asked “Are you thinking about suicide?” Research shows that older adults who die by suicide often visit their primary care physician within a month before their death. Given this finding, primary healthcare providers have an opportunity to initiate a conversation about mental health with their patients and to recommend mental health treatment when indicated [32]. All primary care settings should have suicide screening, assessment, and referral protocols in place [32]. Older adults may also be more willing to receive mental health services on the recommendation of their primary care provider and if the referral is initiated during the visit. To do this effectively may require having a mental health clinician on staff.

To help healthcare providers detect and intervene with potentially suicidal patients, regulatory agencies and professional organizations have developed physician guidelines [32]. The difficulty with this recommendation is that it relies on the patient to honestly disclose their symptoms of depression or their substance use as well as sharing their feelings of distress and despair. While there are no guidelines that are specific for screening older adults who seek treatment from a physician, a broader screening scale should be considered [32]. The Reasons for Living-Older Adults Inventory (RFL-OA) considers age-related factors and consists of 69 questions that clinicians can ask older adults who are at particular risk [16]. This assessment considers protective factors, such as family and religion, as well as personal views on life and death [16].

Prevention

Approaches to preventing suicidal behavior and attempts involve the detection and treatment of high-risk individuals, such as older adults [28]. Given that older adults tend to visit their primary care providers within days to months prior to their death by

suicide, it is important for physicians to be educated in recognizing risk factors [22, 24]. As previously discussed, through increased training and screening procedures, this is one way to help older adults who are distressed and suicidal. However, because primary care providers have limited time designated for each patient visit and older adults' tendency to underreport symptoms, it can be difficult to carry out an adequate assessment [22]. It is easy to imagine a patient making a comment that suggests feelings of hopelessness and having the comment ignored or insufficient follow-up questions. One technique that is being used is similar to a safety plan or contract. This technique is a no-suicide contract that primary care physicians discuss and implement, where the older adult agrees to remain safe until the next scheduled appointment [24]. For some patients, this may be an effective short-term approach. However, this approach is dependent upon the individual taking the agreement seriously, agreeing to using mental health treatment, and is not prone to high impulsivity. An individual who possesses a firearm and uses substances or has a cognitive impairment that decreases reasoned thinking and increases impulsivity may not care about the agreement they made with their physician.

As effective interventions are being developed, prevention programs can be used to address suicide at multiple levels [17]. Prevention can be implemented within the community, medical settings, and with family and friends. Universal prevention targets entire populations by implementing self-administered screenings, limiting access to means, addressing issues related to aging, and providing psychoeducation about risk factors [17]. This is a broad approach and may not be suitable for all populations. In particular, someone with low insight may not benefit from a universal prevention approach. Selective prevention attempts to reduce suicide in those with known risk factors by implementing systematic screening tools in medical and nonmedical settings, utilizing treatment strategies, providing systematic support, and increasing awareness [17]. This approach allows for a more targeted prevention effort but also requires a knowledge of the patient's history, social support, physical health, mental health, and current life stressors. Not all healthcare providers have access to all of this historical and current information. The third category of suicide prevention among older adults is prevention which targets individuals with acute suicidal ideation and attempts [17]. This is both prevention and postvention in that it allows for examining patient history to inform prevention efforts. Again, this requires a level of insight and a motivation to stay alive while experiencing suicidal ideation.

Treatment

Appropriate and effective treatment targeting risk factors and identifying protective factors (reasons for living) is pivotal in preventing suicide in older adults [3]. This is a subgroup of the population that is often unlikely to report their distress and frequently viewed as just "getting older." Therefore, it is necessary for the individuals around them to be vigilant and take protective action. Many of the available evidence-based treatments for suicidal ideation in older adults target depressive symptoms concurrently. A range of psychological treatments have been found to

be efficacious in treating depression and suicidal ideation in older adults [3]. Treatment approaches include reminiscence therapy, problem-solving therapy, cognitive-bibliography, and cognitive behavioral therapy (CBT) [3]. Reminiscence therapy is a useful approach for those who have been diagnosed with dementia and other related neurocognitive disorders. Patients are invited to recall and discuss their memories and past experiences through tangible mediums (i.e., photographs, music, etc.) which helps with meaning-making [43]. Problem-solving therapy, a process of identifying, exploring, and discussing goals, is a promising intervention for older adults at risk for suicide as it aids in reducing impulsivity while supporting effective decision-making skills [21]. Indeed, a problem-oriented approach may also help to destigmatize emotional distress. Cognitive-bibliography therapy is an approach that utilizes the reading of a self-help book as a form of treatment for psychological problems [18].

In general, CBT and safety planning have been found to be effective treatment approaches for depression and suicidal ideation. CBT for older adults is a practical approach with a specific psychoeducational component that targets empowering older adults to apply developed skills outside of the psychotherapy relationship while increasing overall life satisfaction [12]. Safety planning is the process of planning for emotional distress and developing accessible, visible alternative behaviors and has been associated with decreased hospitalizations and decreased suicide attempts [8]. The intervention is a plan for recognizing distress, choosing a safe coping behavior, and eliminating the guesswork of how to cope.

The interventions described above typically target depression as the primary focus with a secondary aim of reducing suicide risk. They may help treat depression symptoms for some patients; however, these approaches do not always sufficiently reduce key indicators of suicide risk, particularly in aging adults [3]. Conti et al. [8] suggest a model that incorporates depression, functional impairment, physical illness and pain, social isolation, and access to lethal means. More research is needed to determine how best to treat suicidal ideation in older adults. After they have screened as having risk factors and are willing to receive treatment, how do we help them remain safe? The goal for suicidal ideation reduction is to promote both physical and cognitive functioning as well as increasing overall well-being [40]. In some cases, this may be enough, but not all older adults can have their physical functioning improved or restored. Not all older adults have cognitive functioning that can be improved significantly. Yet risk for suicide is still present for these individuals. As such, continued effort must be made by the people around them and by experts in the field to find the best practice for older adults who are experiencing suicidal ideation.

Conclusion

Suicide is a growing problem that requires the attention of clinicians, researchers, program developers, and policymakers. Perhaps even more importantly, each individual must adopt some level of vigilance to look out for friends and loved ones who might be at increased risk. Due to mental health stigma, not everyone is willing to

seek help. This can be especially common for older adults who may feel reluctant to share their feelings and concerns. Primary care providers, home health nurses, and family members are often the first line of contact for many older adults. If these individuals can become familiar with the warning signs and best practices of assessing and monitoring for suicide, some older adult deaths could be prevented. It is the responsibility of all health clinicians to monitor and assess the wellbeing of older adults in their care.

In this chapter, both risk and protective factors were presented. Family members could be educated to be more aware of older adults' needs as they continue to age and useful ways to intervene if distress is detected. Isolation and mental health stigma are common. Even if someone was available for an older adult to speak with daily about their concerns, they still may underreport their actual distress. Additionally, the prevalence of physical illness presents factors that affect daily living and could contribute to feelings of hopelessness. Lastly, access to lethal means allows for little-to-no interruption of the thought-impulse-action continuum. The above risk factors could also be helpful to providers who are conceptualizing patient risk. Providers may wish to implement suicide screening procedures when working with older adults. Having a medical professional normalize the use of mental health services could reduce stigma and increase the likelihood of working with a therapist.

Through mental health interventions such as safety planning, cognitive therapy, and problem-solving therapy, many older adults experiencing suicidal ideation may find peace of mind. These treatments, as well as prevention efforts are ways that providers can effectively decrease suicide rates on their caseload. Psychoeducation of the public and provider competency training in suicide assessment can help to destigmatize suicide and perhaps increase the likelihood of older adults seeking help. For those that do not seek help, it is clear that those around them must take responsibility for the wellbeing of their loved ones. Depression and suicidal thinking are not a normative part of aging. Rather, these are mental health conditions which should be treated as such so that older adults can safely and happily continue to live their lives.

Abstract

Around the world, males dominate suicide statistics. Masculinity – socially constructed gender ideals for boys and men – may be a key contributory factor underpinning the heightened risk of suicide in males. Conformity to “dominant” masculine norms like self-reliance is associated with reduced help-seeking in boys and men. If they do seek help, they often find that services are not well matched to their ways of dealing with problems. Addressing the problem from both ends – norming help-seeking and engaging boys and men with effective help – is much more likely to yield success than addressing these long-standing issues separately.

Keywords

Suicide · Males · Men · Boys · Masculinity

This chapter discusses the intractable issue of male suicide. It describes the magnitude of the problem and explores whether the expectations that society places on boys and men to behave in certain ways may heighten their risk for suicide. It then goes on to discuss the kinds of interventions that might be required to address the root causes of male suicide, noting that our knowledge about the effectiveness and cost-effectiveness of these interventions is limited.

Many chapters of this kind would stop there, indicating that further research is needed to fill these gaps. Instead, ours describes a comprehensive program of research that our team is conducting to further understanding whether certain interventions may help to prevent suicide in boys and men. The research program involves a partnership in which a multidisciplinary group of researchers from five universities (University of Melbourne, Monash University, Deakin University, University of Wollongong, and University of British Columbia) is collaborating with 14 community/industry organizations with a strong commitment to male suicide prevention (Australian Men’s Health

Many of these partner organizations are or will be responsible for co-designing and delivering the interventions we will test.

Suicide in Boys and Men

Around the world, males feature prominently in suicide statistics. The World Health Organization collated international suicide statistics in 2014 and found the global rates in high-income countries were 19.9 per 100,000 for males compared with 5.7 per 100,000 for females [1]. The gap was less striking in low and middle-income countries, but male suicides still outnumbered female suicides by a factor of at least 3:2 [2]. In Australia, our figures are consistent with those in other high-income countries. In 2020, 3139 Australians died by suicide, 2384 of whom were males [2]. This put our male suicide rate at 18.6 per 100,000, more than three times higher than the rate of 5.8 per 100,000 for females [2].

Each time we lose one of our brothers, sons, fathers, uncles, grandfathers, or male friends, colleagues, or peers to suicide, there is an enormous ripple effect. It has been estimated that for every person who dies by suicide, around 135 people suffer intense grief or are otherwise affected [3]. In Australia, that's 313,200 a year who experience the heartache of losing a male in their life to suicide. For many, this impact will be devastating and long-lasting [4, 5] and may increase their own risk of suicidal behavior [6, 7].

Masculinity, Seeking and Receiving Help, and Suicide

There are various explanations for the excess suicide rate among males, including that they are more likely to choose lethal suicide means [8], overuse drugs/alcohol, and withdraw in the face of stress [9, 10], and are less likely to seek help [11]. Masculinity – socially constructed gender ideals for boys and men [12] – may be key contributors to all of these explanations. There are multiple masculinities [13], but in many countries, the “dominant” one promotes norms of power, strength, competitiveness, self-reliance, stoicism, independence, and avoidance of negative emotions [14–16]. These norms are often positive, providing some men with a protective buffer against mental health issues [17], but rigid adherence to them may exert an influence on male suicide (e.g., the choice of lethal means may relate to the view that nonfatal suicide attempts are “feminine” or “weak,” [5, 18] and heavy drinking – which is accepted in many masculine milieus [19] – may be a way to manage depression [20–22]).

The interplay between masculinity, help-seeking, and suicidality may also be particularly important. Conformity to masculine norms has been shown to be associated with reduced help-seeking [23–26] and suicidality [27–30]. The influence of masculine norms on help-seeking is in turn mediated by intersectional factors

including age, socioeconomic status, culture and ethnicity, and sexuality. Self-stigma can act as a barrier to help-seeking for men [31], suggesting that interventions that encourage males to seek help may need to challenge rigid masculine norms.

Even when boys and men do seek help, it may not meet their needs. Health services have been criticized for being “gender-blind,” and males often find them inconvenient, unengaging, and inadequate [32]. Mental health services may exacerbate the situation because males doubt that psychotherapy works, don’t feel safe disclosing that they are not coping [33], and/or view treatment as transgressing masculine norms that idealize self-reliance and self-management [34]. A less-than-satisfactory initial experience with services is likely to put males off when it comes to seeking help if they need it in the future [35]. There have been calls to tailor mental health services and the treatments they offer to the specific needs of boys and men, with recommendations that providers consider the impact of masculine norms on consumers, use skills that orient men to health care, adapt their language to include male-oriented metaphors, and utilize collaborative, transparent, strength-based, and goal-focused treatment styles [36].

Suicide Prevention Interventions

Suicide prevention interventions are classified as (1) universal (targeting whole populations and focusing on certain risk factors without identifying individuals with those risk factors); (2) selective (targeting individuals who are not suicidal, but who have recognized risk factors for suicidality); and (3) indicated (targeting individuals who are experiencing suicidal thoughts or behavior) [37, 38]. Often a variety of universal, selective, and indicated interventions are implemented in conjunction with each other, via a coordinated a “systems-based” approach [39]. The idea is that interventions delivered simultaneously across these different levels have a greater chance of bringing about significant, lasting change than interventions delivered in isolation.

Universal/Selective Interventions That Encourage Help-Seeking Through a Focus on Masculinity

Recently, increasing emphasis has been given to interventions that encourage help-seeking via a focus on masculinity. These tend to be universal interventions, delivered to all males in particular settings, through workshops, training, or media campaigns. In Australia, our partner organizations are delivering some prominent examples: *Breaking the Man Code* (run in schools; Tomorrow Man), *Ahead of the Game* (run in sporting clubs; Movember), and *MATES in Manufacturing* (run in manufacturing work sites; MATES in Construction). Some of these interventions have selective elements too (e.g., *MATES in Construction* trains “connectors” and Applied Suicide Intervention Skills Training [ASIST] workers to support at-risk individuals).

Despite their increasing popularity, the evidence base for these interventions is still underdeveloped. There are published examples of pre-/post-evaluations and nonrandomized trials [40], but only one randomized controlled trial has been reported. This was our own trial of *Man Up*, a three-part documentary aired on ABC TV that explored the relationship between masculinity and suicide and encouraged men to seek help. *Man Up* was created by members of our research team with two of our partners (Heiress Films, Movember) and was hosted by Australian radio personality Gus Worland, who then founded another of our partner organizations (Gotcha4Life). Our RCT showed that *Man Up* increased men's help-seeking intentions [41]. A few other relevant randomized controlled trials are underway [42, 43], including one of *Breaking the Man Code* and another of *MATES in Construction*. These latter trials are being led by members of our research team. The focus of all trials to date has been on effectiveness; none have examined cost-effectiveness.

Indicated Interventions That Ensure That When Boys and Men Do Seek Help, It Meets Their Needs

In Australia and elsewhere, far less attention has been devoted to indicated interventions that ensure that when boys and men do seek help, it is appropriate to their needs. A recent review of Australian tertiary medical training programs showed that limited attention has been paid to the role masculinity plays in engagement with and outcomes of treatment [44]. Guidelines have been developed for the Australian Psychological Society, and a psychologists' training program called *Men in Mind* has been created based on consumer and expert consultation and is due for piloting. However, there are very few examples of best-practice services. Those that do exist, like *Mantle Health*, are in their infancy. No randomized controlled trials have been conducted of any services that provide mental health care through the lens of masculinity.

Addressing Research Gaps: Advancing Knowledge by Answering Critical Research Questions

To summarize, we know that in many countries three quarters of all suicides are by males and that conformity to masculine norms may explain this, at least in part through its role in inhibiting help-seeking and norming self-reliance. Universal/selective interventions that encourage help-seeking in boys and men through a focus on masculinity are likely to be of value, but only if indicated services are "male friendly." There is a major gap in our knowledge, however, as to whether these universal/selective and indicated interventions work.

Our team has recently received funding from Australia's Medical Research Future Fund to address this knowledge gap. We are embarking on a 4-year program of research that will answer four critical research questions:

- Are universal/selective interventions that encourage help-seeking through a focus on masculinity effective and cost-effective?
- Are indicated interventions that are tailored to the specific needs of boys and men effective and cost-effective?
- How might these universal/selective and indicated interventions best work together?
- How can they each be optimized and scaled up?

Our Research Program

Figure 1 shows the conceptual basis for the research. The problem we are addressing is that societally imposed dominant masculine norms run counter to at-risk boys and men seeking help and that those who do seek help often do not receive services that meet their needs, leading to negative outcomes. Our research will investigate whether the solution to this is universal/selective interventions that encourage help-seeking through a focus on masculinity, delivered alongside indicated interventions that are tailored to the specific needs of boys and men.

Our research program involves a series of randomized controlled trials (run by our researchers) of universal/selective and indicated interventions (delivered by our partners). Most of these interventions already exist, and although some have even been evaluated, as noted, this evaluation has tended to be minimal. Only two are the subject of current randomized controlled trials, and these trials do not include cost-effectiveness analyses. We are planning to complement the existing interventions with some new or modified interventions that will be co-designed with our partners and males with lived experience of suicidality. The randomized controlled trials will be augmented by modeling exercises which will consider the broader budgetary and societal implications of rolling out the interventions, in tandem, at scale.

Fig. 1 Conceptual framework

The Interventions

We will trial seven interventions (five universal/selective and two indicated; see Fig. 2):

- *Universal/selective interventions*: Three of the universal/selective interventions (*Breaking the Man Code*, *Ahead of the Game*, and *MATES in Manufacturing*) are well-established and encourage help-seeking in boys and men by challenging dominant masculine norms. *Mental Health First Aid – Conversations about Suicide (MHFA-CS)* is a more general training program that promotes help-seeking and help-offering, and we will modify it for use in Men's Sheds (community organizations that advance men's wellbeing in a safe environment where they work on meaningful projects with other men). The *media-based male suicide prevention campaign* is the only universal/selective intervention that we will develop de novo. This will be multifaceted and involve traditional and digital media. The modification of *MHFA-CS* and the development of the *media-based male suicide prevention campaign* will be co-designed with the relevant partners and boys and men with lived experience of suicidality.
- *Indicated interventions*: Both of the indicated interventions are currently in the development stage. A set of *specialist Lifeline services* will be delivered by Lifeline, Australia's largest provider of 24-h crisis support and suicide prevention services. Lifeline will develop a model of service delivery that responds to men's needs, co-designing it with male callers. The specifics of the model are yet to be finalized, but it might include messaging that appeals to males (while at the same time resonating with females). The second intervention is *Men in Mind*, a world-first online training program that offers psychologists evidence-based, interactive modules to leverage therapeutic principles that work for men and incorporate these into the way traditional mental health treatments are delivered.

The Randomized Controlled Trials

We will conduct new trials to test the effectiveness and cost-effectiveness of three of the universal/selective interventions and both of the indicated interventions. Trial of *Breaking the Man Code* is underway, and we will strengthen this by adding an economic evaluation component and expanding the number of participants (to maximize the potential for sub-group analyses). In each trial, the given intervention will be compared with an appropriate control condition (e.g., a waitlist control, a minimal awareness-raising intervention or usual practice).

Most trials will be conducted in the settings in which the interventions are delivered. The exception is the trial of the *media-based male suicide prevention campaign*, which will be run in a "laboratory" setting. In each case, participants will be the target group of the particular intervention.

The primary outcome in each of the trials will relate to what each intervention is aiming to achieve (e.g., increases in participants' likelihood of seeking help,

Universal/selective interventions		
Breaking the Man Code • Intervention status: Existing • Target group: Yr 10-12 boys • Setting: Schools • Format: Workshops • Partners: Tomorrow Man, Gotcha4Life	Ahead of the Game • Intervention status: Existing • Target group: 12-17yo males and their parents and coaches • Setting: Sports clubs • Format: Workshops and online modules • Partner: Movember	MATES in Manufacturing • Intervention status: Adapted from existing • Target group: Manufacturing workers (~75% male) • Setting: Manufacturing work sites • Format: Integrated program of training and support • Partner: MATES in Construction
Mental Health First Aid – Conversations about Suicide (MHFA-CS) • Intervention status: Needs modification • Target group: Older men • Setting: Men's Sheds • Format: Workshops • Partners: MHFA, Victorian Men's Shed Association		Media-based male suicide prevention campaign • Intervention status: New • Target group: Boys and men • Setting: Community • Format: Digital and traditional media • Partners: Heiress Films, Everymind, Gotcha4Life
Specialist Lifeline services • Intervention status: New • Target group: Male Lifeline callers • Setting: Lifeline • Format: To be finalised, but likely to include messaging that appeals to males (while at the same time resonating with females) • Partner: Lifeline		Men in Mind • Intervention status: Existing • Target group: Professional men • Setting and Format: Psychologists receive training program which allows them to leverage therapeutic principles that work for men and incorporate these into treatment. These psychologists deliver services to professional men via a secure phone/video-link format that responds to identified barriers (e.g., self-stigma) • Partners: Movember, Mantle Health

Fig. 2 Interventions

decreases in participants' levels of suicidality). In each case, we will use standardized instruments that we have used in previous trials to assess the outcome (e.g., the General Help Seeking Questionnaire [45] or the Adult Suicide Ideation Questionnaire [46, 47]). We also use the AQoL-4D [48] to derive utility values in order to calculate quality-adjusted life years (QALYs) for the cost-effectiveness analyses (e.g., using the Australian Quality of Life Instrument [48]) and will capture information on resource use and lost productivity through a validated self-report questionnaire and, ideally, through linkage to routinely collected service use data.

The Modeling Exercises

Although “within-trial” economic evaluations will be embedded in each of the trials, there are limits to these. Firstly, important longer-term impacts of the interventions will not be fully captured in the trials because the outcomes measured will be surrogate outcomes relating to, for example, help-seeking intentions, reductions in suicidal thinking and quality of life, rather than the ultimately desired outcome of a reduction in male suicide rates. Secondly, the broader budgetary and societal implications (including scalability cost considerations) of the interventions will not be accounted for.

For these reasons, we will develop a purpose-built lifetime (age 15 to death) economic model, designed to inform decisions about future investments in male suicide prevention. The model will use cost and outcome data from each of the trials to evaluate the population cost-effectiveness of implementing the universal/selective and indicated interventions in combination. It will also draw on empirical analyses of data from longitudinal studies and systematic reviews of epidemiological literature to estimate longer-term trajectories of suicidality and service use in boys and men, along with the resource implications of these.

Strengths and Weaknesses of Our Approach

Our research program will rigorously test a large number of interventions and will therefore exponentially expand the evidence base around male suicide prevention. It is feasible because most of the interventions already exist in some form, having been developed and delivered by our partners. This collaborative participatory action approach also means that if the interventions are found to work, they can readily be scaled up. In addition, these partnerships enable us to channel most of our budget to foster high-impact research and research capacity building, rather than to develop interventions. The existing interventions have been developed with input from stakeholders, including boys and men with lived experience of suicidality, and the new or adapted interventions will be similarly co-designed.

The fact that most of the interventions exist does, however, impose some constraints on trial conduct (e.g., we will need to conduct cluster randomized controlled trials rather than individually randomized controlled trials of most of

the universal/selective interventions because many of these interventions are setting-based). This also makes it difficult to test interventions that *both* encourage boys and men to seek help and provide tailored services for them, although our modeling exercises will explore the impact of delivering the universal/selective and indicated interventions in tandem. Our interventions do not target particular at-risk groups, but the modeling exercise will take subgroups into account via its focus on individual trajectories and our team includes people whose expertise will help us conceptualize how the interventions might be tailored for specific subgroups (e.g., male veterans, Indigenous males; men who are or have been incarcerated).

A Final Comment

Our efforts in this area may be all the more important in the time of COVID-19. Suicide prevention experts from around the world have warned that particular risk factors for suicide may be heightened as the pandemic continues [49], and some of these may be particularly salient for males. For example, the social isolation associated with lockdown may be exacerbated for men with already-limited networks or those whose contact with their male friends relies on activities (e.g., catching up at sporting events). Similarly, the economic consequences of the pandemic may be particularly damaging for working age men who align to breadwinner and provider roles but lose their jobs and careers. We must do all we can to contextualize males' suicide risk and support vulnerable boys and men in these times.

We genuinely believe that our program of work could be game-changing. If we could “crack the nut” of how to prevent male suicide, we would be able to make major inroads into bringing down the overall suicide rate. Addressing the problem from both ends – norming help-seeking and engaging boys and men with effective help – is much more likely to yield success than addressing these long-standing issues separately.

The Workplace: Our Most Crosscutting and Under-Leveraged System in Suicide Prevention and Suicide Crisis Response

27

Sally Spencer-Thomas

Note: This chapter is dedicated to Dr. Allison Milner, an international expert and leading scholar focused on researching workplace suicide and suicide prevention. Dr. Milner died tragically on August 12, 2019, as we were putting the final touches launching the National Guidelines for Workplace Suicide Prevention (USA). Dr. Milner was an inspiration and mentor to many of us who work in suicide prevention in the workplace, and her contributions to the field are unparalleled.

Abstract

Arguably, the workplace is our most crosscutting system for suicide prevention and suicide crisis response. On a daily basis, there are more people impacted by suicide and suicidal intensity showing up to work than there are people intersecting with our healthcare, education, or religious systems. Thus, we have opportunities for prevention and postvention in our workplaces, yet historically, the workplace has not been leveraged in this way. This chapter summarizes

historical theories, case studies, and industry-specific research related to workplace suicide risk and prevention. The chapter concludes by offering a comprehensive strategy based on the U.S. National Guidelines for Workplace Suicide Prevention. This public health approach acknowledges that there are upstream, midstream, and downstream tactics needed to mitigate workplace psychosocial hazards, increase access to mental health supports (including peer support), and respond with dignity and collaboration during employees' psychological emergencies.

Workplace Suicide Prevention · National Guidelines for Workplace Suicide Prevention · Strategy · Crisis response · Training · Postvention · Leadership · Managers · Human resources · Job strain · Psychosocial hazards · Peer support · Mental health · EAP · Lethal means · Industry · Construction · First responders · Healthcare

According to the International Labour Organization, 57% of global citizens 15 years and older are employed [12]; we often spend more waking time working each week than we do with our families. Arguably, the workplace is our most crosscutting system for suicide prevention and suicide crisis response. On a daily basis, there are more people impacted by suicide showing up to work than there are people intersecting with our healthcare, education, or religious systems. Thus, we have opportunities for prevention and postvention in our workplaces, yet historically, the workplace has not been leveraged in this way. Most of the scarce workplace suicide prevention programs that exist have usually not been evaluated [20].

When a workplace is working well, it is often a place of belonging and purpose – qualities of our well-being that can sustain us when life gets unmanageable. Proactive workplaces provide access to needed mental health resources through employee assistance programs and peer support.

Because suicidal thoughts are usually invisible, employers usually assume “it doesn’t happen here” – until it does. Coworkers then are often forgotten grieverers after a suicide. Rarely, until now, did employers consider their role in suicide prevention.

Increasingly, the global community of employers is widening the lens from seeing suicide only within a mental health framework to a broader public health one. In other words, suicide and suicidal intensity are now being seen beyond the symptoms of a mental health condition. Through this broader public health lens, workplaces now understand the importance of a culture that contributes to emotional resilience rather than to psychological toxicity, and they can take steps to create a caring community of well-being.

Why Should Workplaces Care About Suicide Prevention?

Work as a social structure and its relationship to suicide. Over a century ago, Emile Durkheim [7, 8] considered suicide as a society-determined phenomenon in which the role of work played a significant role. Durkheim argued that when

working well, work fosters social relationships and offers people a place of purpose and solidarity. According to Durkheim the place of employment sets a social structure, moral values, and a sense of identity for an individual – all of which helps give the individual meaning and reasons for living. When social structures like work disintegrate, the individual suffers, and sometimes suicide can be a consequence. When workers are only seen as a source of profit or an obstacle to profit, suicidal despair may result due to the disconnection people feel [31].

Over 150 years later, employers across the world are becoming increasingly aware of the need for and benefit of addressing mental health promotion and suicide prevention in the workplace, both from a business cost perspective and from a social responsibility perspective. Awareness has been slow to turn to action because employers are not sure where to begin, how much they need to do, and when they have satisfied their ability in promoting and protecting employee well-being.

The cost of suicides and suicidal behavior on workplaces. Recently, a team of health economists have been studying the costs of suicide and the return on investment of suicide prevention and intervention activities to workplaces and communities. For instance, Doran et al. [6] found that on average the cost of a suicide death of one male construction worker was \$2.14 million, mostly due to the average 27.3 years of productive employment lost. They also determined that for every dollar invested in suicide prevention \$4.60 would be returned to society. Another study [13] measured a number of costs related to suicide and suicidal behaviors including production disturbance (e.g., value of lost production and staff turnover), human capital lost, medical costs, administrative costs (e.g., due to employer investigation), and more. They examined the costs associated with short- and long-term absences after a suicide attempt, full incapacity, and fatality and found a 1.50:1 benefit-cost ratio for investing in suicide prevention. They surmised that if employers were more aware of the economic consequences of the impact of suicide and suicidal behavior on their workplace, they might be more motivated to provide more mental health promotion and well-being initiatives.

Not all suicide prevention is crisis oriented; in fact, proactive efforts may even have a bigger ROI. Just like promoting heart health is less expensive than responding to the crisis of a heart attack, promoting optimal and holistic well-being makes good business sense. Rather than only focus on deficit or symptom-focused models of workplace intervention, many positive psychological resources can also be cultivated like self-esteem, mastery, resilience, and emotional intelligence. Well-being has clear connections to greater employee engagement, proactive work behavior, and transformational leadership [19]. Altogether, promoting protective factors, early intervention, and effective suicide crisis response save companies money and heartache.

Suicide waves in industries and the impacts on companies. In 2012 the Chief Executive of France's Telecom was forced to resign, and six other executives faced legal action taken against the company following an investigation. Charges filed against the company were related to workplace bullying, harassment, and toxic "management-by-terror" practices that were allegedly connected to over 80 employees' suicide attempts or deaths. Several of the suicide notes written by those who went on to die by suicide explicitly identified France Telecom as the sole cause for death due to "intolerable conditions" [31, 32].

In this case, the executives reportedly mandated a number of highly disruptive practices in order to downsize the company. For instance, they repeatedly transferred highly skilled workers to low-level jobs and then relocated the workers, disrupting their families. The communication around these transitions was infused with guilt and fear and pitted workers against one another. These former professional technicians were often placed in humiliating situations where they needed to ask permission to use the toilet [31, 32]. Once questioned about the suicides (which reached a peak in 2010 with 27 deaths), the leaders resorted to concealing or denying the deaths or rationalizing them as individual anomalies to keep hidden from public view.

Around the same time, another similar suicide wave emerged in a different part of the world. China's Foxconn, a telecommunications company that supports the manufacturing of Apple products, also experienced a suicide cluster in 2010 and underwent highly public scrutiny. Here, instead of highly skilled professionals, the victims were often migrant workers displaced from their rural communities to work manual labor under poor conditions [32]. At one point 300 workers allegedly took to the roof of Foxconn and threatened to jump unless they were treated more fairly.

Other "suicide waves" connecting work to suicidal despair have been noted in other cultures and industries including Australian miners, British bankers, Indian farmers, and Japanese managers. In fact, the Japanese even have a word describing suicide from overwork – *karo-jisatsu* – and consider the problem an urgent public health issue [32]. The United States has also seen surges of highly publicized suicide deaths related to work including numerous banker deaths in 2015 [26] and a current surge in first responder suicide deaths [10].

Job strain and suicide. Toxic work demands and negative employee perceptions of the work environment have been historically underappreciated in the conversation about suicide prevention; however, research connects a number of job stress-related factors to risk of suicide death and attempts, even when controlling for mental health problems.

Howard et al. [11] examined the "perceived reality" workers had about certain job design characteristics and threats to personal resources and determined that several indirectly contributed to the risk of a suicide attempt including:

- Lack of job autonomy
- Lack of job variety
- Work-family conflict (i.e., work demands make family responsibilities more difficult)
- Family-work conflict (i.e., family demands make work role challenging)
- Heightened job dissatisfaction and the feeling of being "trapped"
- Work that was not meaningful or intrinsically rewarding

The increased attention to "mental health literacy" at work may in part be a deflection away from the importance of these findings. If workplaces believe that the mental health symptoms and suicide crises are only due to untreated or mistreated mental illnesses, they may be engaging in a "state of denial" about their own

systemic contribution to the problem [32]. One tactic used to minimize workplaces' role is by medicalizing suicide as being the sole result of individual psychopathology rather than anything linked to work conditions [32].

Workplace fatalities. Worker safety is a core value in many industries, and thus safety directors routinely pay attention to trends in workplace morbidity and mortality. Because most suicide deaths do not occur at a worksite, suicide has not historically been “on the radar” of safety professionals. When a workplace fatality happens, the cause is almost always determined to be “accidental,” and a deeper investigation into intent to die is not undertaken. Because this deeper investigation is not done, the only remedy suggested is more safety training. While safety training will help those who did not intend self-harm, it will not benefit those whose death is intentional.

When we look at the fatal occupational injuries [3], the first two most common (transportation incidents and falls) are also common ways people think about taking their lives [4, 5]. Thus, it is possible that some if not many of these workplace fatalities are actually suicide deaths, which then means that safety training may not be effective in preventing them.

Specific industries at heightened risk. Not all workplaces are created equal when it comes to suicide risk. In some situations, it is the demographics and risk factors of the types of workers coming into certain occupations (e.g., industries comprised of a majority of men), in other situations it is the nature of the work that increases risk, and often it is a mixture of the two.

While self-reliance is often valued as a sign of strength and mental stability, it is paradoxically one of the strongest predictors of poor mental health and suicide risk [1, 9, 16, 18]; thus, industries that value self-reliance are often at heightened risk. Attitudes and beliefs like “I can solve my own problems” and “others do not need to worry about me” are often a major barrier to seeking support from family, peers, or professionals.

Thus, it is not surprising that occupations that are male-dominated and value stoicism and traditional masculine norms like construction and extraction have the highest rates (53.2/100,000 for men in the United States) of suicide. In fact, in one US study looking at suicide and occupation [24], 20% of the male suicide decedents from 17 states were in the construction/extraction industry. The study went on to suggest that tailored suicide prevention approaches would be needed for these types of industries – both efforts related to promoting early identification and help-seeking and improving working conditions.

An Australian study [21] found that proximal risks to the construction workers' suicide deaths included a transition in work experiences, a workplace injury resulting in pain or disability, and financial issues. The study also found that the decedent often disclosed to coworkers about suicide plans prior to death, indicating that peer support could be a life-saving intervention.

Some other industries also have unique risk factors, such as access to lethal means among law enforcement and exposure to trauma in protective services and some health services. For instance, the workplace suicide rate (suicide at the worksite) for protective service is 3.5 times greater than the overall US worker rate; 84% of these

suicide deaths involved firearms [29]. Female physicians' suicide deaths are 130% percent higher compared to females in other professions; male physicians' risk of suicide is 40% higher than males in other professions [25]. Like with law enforcement, this disparity may result in part from greater knowledge of lethality of drugs and easy access to means. Veterinarians also have suicide rates that are significantly higher than the general population [30], and some speculate this is in part due to their unique role in euthanizing animals, thereby increasing their exposure and reducing their fearlessness to death.

Another international study [15] found that agricultural, forestry, and fishing workers had higher risk and speculated that in addition to having the trait of high self-reliance, these workers were also socially isolated. These workers experienced highly physically demanding work (possibly resulting in acute and chronic pain), excessive work hours, and exposure to toxic/potentially lethal substances (i.e., pesticides). Finally, they were often at the whim of weather or economic disruption that impacted their ability to sustain profitable enterprises.

In summary, the issue of suicide and the workplace is complicated and nuanced. The only way to truly address these issues with integrity and sustained purpose is to use a system-wide, broad-based, and comprehensive approach. Employers and professional associations must be educated to see the benefits of addressing these issues comprehensively, with tools, resources, and training that support this continuous broad-based approach. Fortunately, the United States can learn from other nations who have already been building guidelines for workplace suicide prevention.

Global Models of Workplace Suicide Prevention Guidelines

Canada. Canada has had a "National Standard of Canada for Psychological Health and Safety in the Workplace" since 2013 [17]. The National Standard of Canada on Psychological Health and Safety in the Workplace (the Standard) was sponsored by the Mental Health Commission of Canada (MHCC) and project managed by the Canadian Standards Association. Its broad scope addresses cultural change through evaluation and implementation related to 13 psychological risk areas using a psychological health and safety management system which addresses issues upstream, midstream and downstream. In the first 4 years, there were over 25,000 downloads.

Australia. In Australia in 2014, suicide prevention was the focus of a position statement created by the Suicide Prevention Australia, a nongovernmental organization. The position states made the business and social case for addressing suicide prevention in the workplace, with midstream and downstream directives presented. Later the National Mental Health Commission and the Mentally Healthy Workplace Alliance [23] reviewed the research and identified six key areas [22] and strategies for creating mentally healthy workplaces:

- Smarter Work Design: More flexibility, greater individual and team input into decision-making, harm and hazard reduction

- **Build Resilience:** Training on stress management for high-risk jobs using evidence-based approaches, increasing physical activity, and providing opportunities for mentoring and coaching
- **Support Recovery:** Helping employees reintegrate and get support during and after stressful life events and challenges with mental illness, having generous sick leave and accommodations
- **Build Better Work Culture:** Senior leadership engagement, mental health education, zero tolerance for bullying or discrimination, a climate of safety, mental health education, and change management that has open and realistic communication
- **Early Intervention:** Well-being checks, ability to seek help easily and early, evidence-based training for providers, opportunities for peer support
- **Increase awareness:** Promoting mental health resources, trainings, and programs, participating in community and national events and campaigns.

The 2020 Workforce Strategy Policy Position Statement of Suicide Prevention Australia goes on to recommend three incremental strategies to strengthen the workforce: (1) industry-specific peer support, (2) training community connectors or ‘gatekeepers, and (3) to become enrolled in the national alliance of business groups, unions, or community organizations who are implementing suicide prevention best practices.

The well-established Australian program called MATES in Construction sets the gold standard for developing an evidence base supporting its effectiveness. The program is a large-scale multicomponent suicide prevention program for construction workers, which began in Queensland in February 2008 under the leadership of Jorgen Gullestrup. In addition to ROI studies [6], the program demonstrated that a one-hour general awareness training that highlighted an understanding of suicide and mental health, offered support, and encouraged help-seeking/help-giving resulted in significant positive shifts in attitudes [14].

United States. After almost a decade of research and development, in 2019 the National Guidelines for Workplace Suicide Prevention were launched through a collaborative effort among the American Foundation for Suicide Prevention and the United Suicide Survivors International. The Guidelines evolve within an interactive community of practice found at www.WorkplaceSuicidePrevention.com. Here, employers and professional associations become “pledge partners” and take action steps to become suicide-informed.

Within the National Guidelines are eight Guiding Principles, Values, and Assumptions designed to help workplaces and professional associations build a comprehensive and sustained strategy.

1. *Strategic Integration:* Workplaces are a uniquely positioned and necessary part of a larger public health approach to suicide prevention, and as such they can systemically embed suicide prevention within health and safety priorities.
2. *Comprehensive and Sustained Investment:* “Upstream, midstream and downstream” approaches are all important and require adequate investment of time and financial resources.

3. *Harm Reduction*: Workplaces owe employees a safe and healthy work environment and can strive to decrease the harmful exposures and psychosocial hazards that increase the risk of suicide.
4. *Culture Cultivation*: Workplaces can offer protection from suicide by cultivating connectedness and healthy and caring community that looks out for one another. Leaders drive this culture by recognizing and rewarding these values.
5. *Dignity Protection*: Workplaces can prevent despair and promote healing by fighting against bullying, harassment, discrimination, and prejudice and can uphold dignity with collaborative and respectful reintegration.
6. *Well-being Promotion*: In suicide prevention it's not good enough to focus on pulling people back from the brink; workplaces also contribute to enhanced hope, purpose, and identity that gives people reasons for living and provides a pivotal role in recovery.
7. *Empowered Connection*: Workplaces can provide or connect to accessible and effective treatment and peer support services and can prepare employees to help compassionately link people to care.
8. *Action Orientation*: Awareness is necessary but not sufficient for change. Workplaces must engage in action through policy, training, and other tactics listed throughout the report.

The goal of the National Guidelines for Workplace Suicide Prevention is to increase mental wellness and resiliency and reduce the incidence of and the disruptive and potentially lethal consequences of toxic job strain and undertreated mental health concerns through a focus on:

- *Upstream: Build Protective Factors*: to prevent the problems from happening in the first place by promoting life skills, community, and mental health/suicide prevention literacy
- *Midstream: Early and Effective intervention*: to identify problems early in the course of their development, correct environmental hazards, and connect people who are suffering to qualified supports efficiently
- *Downstream: Safe and Compassionate Responses to the Aftermath of Mental Health and Suicide Crises*: to follow best practice guidelines to reduce the impact of suicide, suicide attempts, and other mental health crises while promoting dignity and empowerment for all impacted.

The National Guidelines offers a comprehensive and action-oriented approach to suicide prevention and postvention and is organized around nine practices – three upstream, three midstream, and three downstream.

Upstream

1. *Leadership: Cultivate a Caring Culture Focused on Community Well-Being*: Create a healthy and caring community and foster genuine community support

and a sense of belonging. Engage leadership around a mindset that mental health and suicide prevention are important pieces of the overall health and safety concerns of the community.

2. *Assess and Address Job Strain and Toxic Work Contributors*: Reduce certain environmental aspects of job strain, burnout, stress, trauma, and life disruption that impact negatively employee vibrancy.
3. *Communication: Increase Awareness of Understanding Suicide and Reduce Fear*: “Bake in” messaging around suicide prevention, mental health promotion, and resilience wherever health and safety messaging is happening. Share stories of recovery, resilience, making-meaning, and support to create a more powerful tale and humanize the issues.

Midstream

4. *Self-Care Orientation: Self-Screening and Stress/Crisis Inoculation Planning*: Help people self-detect emerging suicidal thoughts or mental health concerns (e.g., depression, anxiety, anger, and substance use issues) early in the development of these problems and link people to helpful resources and supports. Teach people to plan for crisis before they are in crisis.
5. *Training: Build a Stratified Suicide Prevention Response Program*: Offer a tiered approach to training that builds skills and confidence at different levels of intensity. Develop specialized training by role for people in a position to offer advanced intervention (e.g., managers or human resources). Provide ongoing training on skills like emotional regulation, conflict resolution, stress management, communication skills, financial planning, goal setting, etc.
6. *Peer Support and Well-Being Ambassadors – Informal and Formal Initiatives*: Enroll peers, ombudsmen, and ambassadors to increase awareness of and comfort with mental health and suicide prevention resources, improve positive coworker assistance, and normalize help-seeking and help-giving behavior with an emphasis on least restrictive peer support, collaboration, and empowerment.

Downstream

7. *Mental Health and Crisis Resources: Evaluate and Promote*: Provide highly trustworthy mental health services well-versed in state-of-the-art suicide risk formulation, management, and support and a range of evidence-informed treatment options. Promote these resources through multiple distribution channels frequently over time.
8. *Mitigating Risk – Access to Lethal Means and Legal Issues*: When potential for suicide is high, collaborative negotiate reduced access to guns, pills, and other suicide means, especially if accessible through job duties. Address workplace legal concerns with issues like privacy, liability, and others.

9. *Crisis Response – Accommodation, Reintegration, and Postvention*: Follow crisis management procedures and longer-term support in the aftermath of a suicide or mental health crisis [2].

To date upwards of 1000 workplaces and professional associations have pledged to make suicide prevention a health and safety priority at work. In September 2020, the Guidelines partners launched a “badge” program where organizations are recognized and rewarded for completing initial action steps within the nine practices.

Conclusion

While we have known that the workplace is a factor in suicide risk and protection for centuries, only recently have we begun to intentionally leverage workplaces as a system for suicide prevention and crisis response. The global effort for workplace suicide prevention is gaining momentum with many countries developing national standards, guidelines, and position statements. What is needed goes beyond a one-off training or awareness day – proactive workplaces and professional associations realize that a comprehensive and sustained strategy is essential (see Logic Model in “[Appendix](#)”).

In essence more workplace leaders are realizing it is time to “Be vocal, be visible, be visionary. There is no shame in stepping forward, but there is great risk in holding back and just hoping for the best” [28].

Abstract

Severe mental disorders have a central role as a risk factor for suicide and as targets of prevention. In psychological autopsy studies, between one-half and two-thirds of suicide have suffered from unipolar or bipolar mood disorders, and a significant minority of subjects have been psychotic at time of death.

Representative national register-based studies have found about 40% of all suicides to be by people who have at some point in their lives been psychiatric inpatients. A meta-analysis found about 4% of all suicide to occur during psychiatric hospitalization, but 18% to have been inpatients during the preceding year. Vast national diagnosis-specific register-based cohort studies show about 2–8% of inpatients with unipolar depression, bipolar disorder, or schizophrenia to have died by suicide. However, such estimates do not necessarily generalize to outpatients, depend on time and context, and may vary over time. In all the three patient groups, incidence of suicide has been shown to be extraordinarily (standardized mortality ratios exceeding 100) high during the first week of psychiatric admission or first week after hospital discharge, declining steeply thereafter. Of all risk factors for suicide deaths, preceding suicide attempts, male gender and comorbid substance use disorders are the most consistent.

Suicide · Schizophrenia · Bipolar disorder · Depression · Psychiatric

Introduction

Suicide is an important cause of death, and in the Global Burden of Disease (GBD) Study, about 1.5% of all deaths worldwide in 2016 were by suicide [1]. Thus, annually worldwide almost 800,000 people take their own lives. Factors underlying suicides are complex, with multiple relevant domains of risk factors, and many valid perspectives for both scientific explanation and prevention. Suicide deaths form only the tip of an iceberg; for every suicide death, there are approximately 20–30-fold numbers of nonfatal suicide attempts, for any attempt, a 5–10-fold number of those with serious suicidal ideas and plans. Although the global suicide mortality has declined by a third between 1990 and 2016, the total numbers of suicides are still increasing due to population growth [1].

Severe mental disorders are central for suicide prevention. According to numerous psychological autopsy studies [2, 3], particularly to those in European and North American settings, almost all (~90%) subjects have suffered from some – usually multiple – mental disorders at time of death. Of all completed suicides in high-income countries, one-half to two-thirds are by people who have suffered from mood disorders, a significant minority from psychotic disorders, and up to one-half from substance use disorders, most commonly of alcoholism or polysubstance abuse. Findings from low- and middle-income countries (LMIC) are broadly similar, but proportion of subjects with mental disorders is highly variable and often lower [4]. Controlled psychological autopsy studies find 4–14-fold suicide risk for subjects with mood disorder [5]. Moreover, a recent national Danish study [6] found 41% of all suicides in Denmark to be subjects who have been psychiatric inpatients at some point in their lives. A systematic review found one-quarter of suicides having been in contact with mental health services during the year preceding suicide [7]. Thus,

prevention of suicides by subjects suffering from severe mood or psychotic disorders is a key issue for suicide prevention overall [8, 9] and therefore comprises the main foci of this review.

Monitoring suicide mortality, knowledge of risk factors for suicide, and provision of adequate treatment for patients with these disorders are central tasks. As suicides tend to cluster on the more severe mental disorders and psychiatric care is the setting where these are treated, role of psychiatric settings is central for suicide prevention. Given limited space, I will focus on three central patient groups, those with depression, bipolar disorder or schizophrenia, and findings pertaining suicide deaths rather than nonfatal attempts. According to a recent meta-analysis [10], pooled suicide rate for people with these serious mental disorders was estimated at 313 (95% c.i. 230–407) per 10^5 person-years in 41 studies published worldwide. Thus, it is order of magnitude higher (28-fold) compared with the global general suicide mortality estimated at 11.1 per 10^5 by the GBD study [1].

Although risk factors for nonfatal suicidal behavior and suicide deaths overall have been vastly investigated, diagnosis-specific rate and risk factors of suicide deaths are less well known. Suicides are rare events, and investigating their illness-specific rates and risk factors necessitates massive patient samples. Advances have been made in the knowledge of risk factors for suicide, and this information has been condensed into risk estimates in important meta-analyses [11–13]. However, due to limitations of the samples available, uncertainty of importance remains for many important risk factors. Research on nonfatal suicidal acts can form an important proxy for studies of suicide deaths and complement view of significant risk factors, but studies of suicide deaths are needed for confirming generalizability of findings between the populations. Therefore, national-level or other representative large-scale studies are necessary for research on risk factors for suicide in severe mental disorders.

Case Definition: Who Is a Psychiatric Patient?

As this review concerns suicide rates and risk factors among psychiatric patients, it is essential to note about importance of case definition. Although defining who is a psychiatric patient may appear self-evident, it is not. The populations included under the rubric may differ markedly. First, the way health care is organized and funded varies widely, as well as density and availability of psychiatrists, or important aspects of legislation. Psychiatric services may be organized as part of national public health care services or as health-insurance-based private services, and public and private services commonly coexist. Private services may or may not be included into the available registers. Therefore, the characteristics of populations served and availability of meaningful data can be highly variable. Second, there are important national secular trends related to deinstitutionalization, expansion of outpatient services, and treatments available. Therefore, temporal context of study matters. Third, clinical epidemiology differs significantly between severe and common mental disorders. While in most countries subjects with schizophrenia or other

psychoses are treated in public sector psychiatric settings, the majority of those with depression are commonly treated in primary health care, and those in psychiatric care represent a subgroup. Fourth, populations of psychiatric patients may include either in- or outpatients or both, and either only those currently receiving care, or subjects who have sometimes received psychiatric services. In particular, major national register-based suicide studies typically include cohorts of inpatients followed-up for years or decades, and information on their current treatment setting, if any, is usually missing. Therefore, it is important to be explicit about settings, definitions, and characteristics, and consider their role in differences of outcomes. Generalizability of findings related to incidence and prevalence of endpoints, or predictive values of risk indicators from one setting to another, remains somewhat uncertain.

Studies on rate and risk factors for suicide deaths necessitate vast patient cohorts. Literature on these unavoidably relies on settings, from which such data is available. For example, due to availability of extensive health care and other population registers plus a personal identification number allowing record linkages in the Nordic countries – Denmark, Finland, Iceland, Norway, and Sweden – vast national-level studies of suicides in mood or psychotic disorders are feasible [14]. Such studies can provide relatively unbiased, generalizable information on suicide rates and risk factors relative to the general population. Overall, the available literature comprises mostly Western European and North American studies. Systematic reviews and meta-analyses effectively condense the available worldwide data and will be reviewed below.

Suicides in Psychiatric Hospitals

Patients are commonly referred to psychiatric hospitals, often involuntarily, in order to protect them from their self-destructive intentions. Thus, hospitalized patients are a highly selected group of subjects with often immediate risk of suicide, and concurrently suffering from illness episodes of severe mood or psychotic disorders. While suicide prevention is a central task during a hospitalization, suicide mortality in psychiatric hospitals has been remained during the last few decades. In part, this is due to deinstitutionalization, which has been a worldwide trend since the 1980s and resulted in a smaller number of hospital beds and shorter hospital stays, even though wide variations in these exist. Thus, the threshold for hospitalization has become higher, and as a group, the patients and their conditions have become more severe. This is a likely explanation for the fact that overall incidence suicides in psychiatric hospitals have not generally declined, despite preventive efforts. A meta-analysis [7] shows about 4% of all suicide to occur during psychiatric hospitalization, but 18% to have been inpatients during the preceding year. Thus, from a perspective of prevention, even more important than the role of inpatient suicides is the significance of recent discharge as an indicator of a patient belonging to a group of individuals with very high risk.

A recent Danish national inpatient suicide study [6] of the years 1995–2016 investigated suicides during and after psychiatric hospitalization. It found the incidence during the first week of admission to be extremely high and comparable to the known high-risk period of the first week after discharge (Fig. 1). The by far highest first-week incidence was among males with depression, the second among males with anxiety and stress disorders. The first-week incidence was lower but still remarkably high for females of the respective diagnostic groups, or those with schizophrenia spectrum disorders or bipolar disorder, of whom a great proportion are hospitalized for mania involving lower risk than depressive or mixed episodes. The rate of suicides declined markedly after the first week, mostly approaching outpatient rates over time.

Risk factors for hospital suicides can be reasonably expected to be the same as for suicides overall, but with some specific features. A meta-analysis of risk factors for suicides during psychiatric hospitalization [15] found a history of deliberate self-harm, hopelessness, feelings of guilty or inadequacy, depressed mood, suicidal ideas, and a family history of suicide-significant risk factors. Patient categorizations according to their estimated risk were found to be associated with very high risk, but positive predictive value of high-risk status nevertheless remained low.

A central preventive issue is controlling availability of lethal means in the hospital environment, e.g., eliminating possibilities of hanging or jumping. Whether or not locking psychiatric wards for safety is necessary is major policy issue. A vast German observational study [16] found no difference in risk of suicide death between locked or unlocked wards. However, this may depend on and vary by setting. A common finding is that at least 40% of hospital suicides occur during approved or unapproved leaves from the hospital [17]. Hospital staff is in a difficult position in trying to evaluate, when a patient's condition allows temporary leave from the hospital. It is further complicated by lack of last visit or last day communication of suicidal intent, which has been shown to be a common occurrence in cases of suicide in psychological autopsy studies [18]. Suicides may also be triggered by unanticipated negative events occurring during the leaves in home environment, risk of which remains unavoidable.

Fig. 1 Incidence Rates of Suicides During Psychiatric Hospitalization in Denmark 1995–2016. (From Ref. [6])

Suicide risk is well known to be extraordinarily high immediately after discharge from psychiatric hospital, and then gradually decline over time (Fig. 2). Overall, incidences during the first weeks after admission or first week after discharge are comparable [6, 19]. In a recent meta-analysis, the pooled estimate for suicide rate during the first postdischarge week was 2950 per 10^5 person years, and 2060 during the first month [19]. Due to differences between diagnostic groups, research findings are reviewed by diagnosis in the following paragraphs.

Suicides Among Depressive Patients

Suicide Deaths in Unipolar Depression

Early estimates for accumulating suicide mortality in major mood disorders were as high as 19% [20]. However, there were significant limitations both in the available data as well as methodology, and the high estimates are incompatible with prevalence estimates of depression in the general population. Already 20 years ago, researchers suggested [21] an epidemiologically conceivable gradient of lifetime suicide risk (case fatality prevalence) from general population 0.5% to 8.6% among suicidal psychiatric inpatients. Nevertheless, scarcity of representative contemporary diagnosis-specific data is a major problem, despite a great need for monitoring rates of suicide in these central patient groups.

Several Nordic national studies have reported on rate and risk of suicide in unipolar depression [22]. They have found between 2% and 8% of psychiatric inpatients with depression to have died by suicide between the 1970s and early 2010s. Of these national studies, the Danish study by Nordentoft et al. [23] was the most long term (median follow-up 18 years), following all subjects treated in a psychiatric hospital or as outpatients in Denmark [23]. It found lifetime risk for men with depressive disorders 6.7% and for females 3.8%. In the longest clinical follow-up study reported thus far, Angst et al. [24] found 11.1% of Swiss inpatients with mood disorders treated in the late 1950s to early 1960s to have committed suicide in 40–44 years. All such estimates unavoidably reflect treatments available during the past decades, not outcomes of patients treated in current settings. As an important demonstration of marked temporal trends in suicide mortality of psychiatric patients, a recent Finnish national study [25] demonstrated decline of hazard ratio for suicide to 0.48, i.e., halving of risk among depressive inpatients between 1991 and 2014. Thus, all mortality estimates are bound to their societal and temporal context, and they can and they do change over time.

Temporal Variations in Suicide Risk During Hospitalization and After Hospital Discharge

According to a recent meta-analysis [10], pooled suicide rate for people with major depressive disorder was estimated at 534 per 10^5 person-years. However, the estimate was based on only four studies and represents averaged incidences of

Fig. 2 Incidence rates of suicides after discharge from a psychiatric hospital in Denmark 1995–2016. (From Ref. [6])

suicide in studies with variable durations of follow-up. Suicide rates among patients with depression vary markedly depending on type of subgroup, treatment setting, and phase of treatment.

Besides psychotic features and functional incapacity, imminent risk of suicide is a key indication for psychiatric hospitalization among subjects with depression. Despite all preventive efforts in hospitals, within this high-risk group and during such a high-risk period, incidence of suicide is remarkably high. In the Danish national study by Madsen et al. [6], the highest first-week incidence (5713 per 10^5 person-years) was among males with depression, and it was remarkably high also for depressive females (1710 per 10^5 person-years), remaining somewhat lower but still high throughout the hospital period.

The transition from protected hospital environment back to home and community is for long known to involve extraordinarily high risk, particularly immediately after the discharge. During this period, the suicide rates have a strong relationship to time elapsed since discharge, and these findings hold worldwide [26]. In the Danish national study [6], incidence of suicide was extremely high during the first week (4554 per 10^5 person-years among males and 2197 per 10^5 person-years among females), exceeding the rates of latter part of hospitalization (males) or hospital period overall (females). The rates declined over time, remaining exceedingly high during the first 3 months, and still high during the whole first year. In a Swedish national study from 1973 through 2009 [27], suicide rate among depressive inpatients in the first month after discharge was 3600 per 10^5 patient-years. Several other national Nordic studies have made similar findings, although with less accurate temporal resolution [22]. The relative risk of suicide among depressive inpatients has been consistently found extremely high ($\text{SMR} > 100$) during the first weeks postdischarge, declining then over time to approximately SMR of five after 5 years of the last hospitalization [6, 22].

Although the postdischarge treatment phase is a well-known period of high risk of suicide across diagnostic groups, the documented role of illness factors needs to be noted. Haglund et al. [27] found marked differences in rates between diagnostic groups. After the immediate postdischarge weeks, suicide risk generally steeply declines over time, typically reaching a level of about fivefold suicide mortality when over 5 years has passed after the last hospitalization [20]. These temporal patterns are important for suicide prevention. There is a time window of very high risk to which preventive efforts need to be focused. However, it is somewhat surprising that, despite this well-known high-risk period and availability of large-scale data, short-term risk factors during this period have remained relatively little studied, with few consistent useful findings [28] beyond preceding history of suicide attempts being an important indicator of risk.

Risk Factors for Suicide Among Subjects with Depression

Information on risk factors for suicide death among patients with depression is relatively limited. The register-based Danish national longitudinal study [23] found male gender, history of a suicide attempt, and comorbid substance use disorder all associated with higher risk of completed suicide in unipolar mood

disorders. Prospective clinical cohort studies of patients with mood disorders have found risk factors for completed suicide to include male gender, family history of suicide, previous suicide attempts, hopelessness, suicidal ideation, psychotic symptoms, comorbid personality disorders, alcohol dependence or misuse, and anxiety disorders. A systematic review by Hawton et al. [11] confirmed the role of these risk factors, except psychotic symptoms and suicidal ideation not reaching statistical significance. The Nordic national studies reporting on risk factors for suicide [22] consistently found male gender, preceding suicide attempts, high severity of depression, and substance abuse risk factors for depression in long term. Aaltonen et al. [29] in Finland investigated also gender differences in 13 risk factors, finding only small differences in them, but major differences in lethal methods used. A Danish study [30] focused on psychotic versus severe nonpsychotic depressions, finding no excess risk due to psychotic symptoms per se.

Some psychological autopsy studies have specifically focused or reported on suicides with mood disorders, and largely concordant findings [31]. Almost all suicides with major depression have significant psychiatric or somatopsychiatric comorbidity. Of specific comorbid disorders, particularly substance use disorders and borderline personality disorders are prevalent. Impulsive-aggressive are important risk factors among suicides among young adults, particularly males, whereas the role of concurrent physical illness is more important among the middle-aged or elderly. Adverse life events, particularly losses, are the typical psychosocial context of suicide. Multiple stressors, some perhaps precipitating mood episodes, others more likely triggering the act, appear common among suicides by subjects with mood disorders [31].

Prevention of Suicides Among Depressive Psychiatric Patients

In most countries, psychiatric facilities are responsible for the severity of depressive disorders, typically of moderate, severe, and psychotic depressions. Therefore, emphasis in their treatment is relatively more in biological treatments rather than psychotherapeutic interventions, as in milder depressions. Although there are effective treatments for depression and they are plausible means of suicide prevention, there is little if any direct evidence for that. These questions are central for suicide prevention in severe mental disorders. In Finland, suicide mortality of inpatients with depression has halved from the 1990s to the 2010s [23]. Whether or not this has to do with improvements in care remains unknown.

Suicides Among Patients with Type I or II Bipolar Disorder

Suicide Deaths in Bipolar Disorder

Rates and risk factors for suicides and suicide attempts among patients with bipolar disorder have been systematically reviewed by the ISBD Task Force for suicide prevention in 2015 [12, 32]. The reported incidences varied markedly but were on average 164 (95% c.i. 5–324) per 10⁵ person-years, and risk was 1.7-fold among

males [32]. According to a more recent meta-analysis [10], pooled suicide rate for people with bipolar disorder, based on 16 studies, was estimated at 237 per 10^5 (95% c.i. 160–329). Also according to this meta-analysis, risk of suicide was twofold (relative risk 1.88) among males compared to females.

Several Nordic national studies have reported on accumulating lifetime incidence of suicide in bipolar disorder. In general, these studies found 4–8% of their bipolar patients having died by suicide [20]. However, all these studies reflect suicide mortality almost exclusively of inpatients and mostly in the past decades from 1970s to 1990s onward. In all the Nordic countries, suicide mortality has markedly declined since the 1990s, and whether or not these estimates from different treatment eras reflect current realities remains open. For example, an outpatient study based on the national Swedish quality register [33] found significantly lower suicide mortality in 2004–2014 among the bipolar patients included, 1.14% among males and 0.44% among females during a median follow-up of 3.8 years. Thus, accumulating suicide mortality may be lower in out- than inpatient settings, and currently than during the preceding decades. None of the studies has been able to examine possible differences between type I or II patients in rates of suicide deaths. The ISBD Task Force meta-analysis found no difference between these subtypes in rate of suicide attempts [12, 32].

Rate of suicides is very strongly related to phase of illness and treatment. Incidence of suicide in the first weeks after discharge from a psychiatric hospital has been consistently found to be very high, even over hundred times that of the general population. In the Swedish national study from 1973 through 2009 by Haglund et al. [27], suicide rate in the first month after discharge was among bipolar inpatients 1740 per 10^5 patient-years. In the Danish national study [6], incidence of suicide during the first postdischarge week was 2338 per 10^5 patient-years among male and 1434 among female bipolar patients, declining steeply thereafter as among inpatients with depression. Findings from Finland [34] are broadly similar, and the Nordic findings in accordance with the broader international literature [19]. Although the postdischarge treatment phase is a well-known period of high risk of suicide across diagnostic groups, the documented role of illness factors needs to be noted. Isometsä et al. [32] found marked differences in temporal patterns of risk between hospitalizations for different types of index episodes among bipolar patients, the risk being highest among those hospitalized for a depressive episode, and among those who had recently attempted suicide. After the immediate postdischarge weeks, suicide risk generally steeply declined over time. Like in unipolar depression, short-term risk factors during this period have remained little investigated. However, preceding suicide attempts are a strong indicator of severalfold risk during the postdischarge period [34].

Risk Factors for Suicide in Bipolar Disorder

In the ISBD Task Force meta-analysis of risk factors for suicide in bipolar disorder [11], only male gender and positive family history for suicide were found significant risk factors for suicide in bipolar disorder. Three national Nordic studies [21, 31, 32]

found male gender, preceding suicide attempts, and hospitalization for depressive and mixed episodes to associate with risk. In addition, the Swedish quality register study [33] found male gender, living alone, criminal conviction, previous year depressive episodes, psychiatric comorbidity (substance abuse, anxiety, or personality disorders), and severity indicators of psychiatric history (inpatient treatment, involuntary commitment) as risk factors for suicide.

Longitudinal clinical studies [12, 32, 35] of patients with bipolar disorder have demonstrated the importance of illness course for risk of suicidal acts. Suicide attempts cluster into depressive and mixed illness episodes. They are also associated with anxiety, substance use, and borderline personality disorder comorbidity.

Role of Lithium Treatment in Suicide Prevention

Numerous observational studies and a limited number of randomized treatment trials suggest long-term lithium treatment to reduce suicide rates. Whether or not lithium reduces risk more than other evidence-based treatments still remains somewhat uncertain [32, 36]. While the reduced suicide rate among those receiving lithium in long term has been amply documented and is highly consistent, the role of various underlying factors still remains unclear. As lithium is toxic in overdose and necessitates adherence to laboratory monitoring, patients for whom it is prescribed probably are a selected subgroup of patients able to comply with such a regimen. There are also quite few major randomized studies comparing lithium with alternative treatments, and observational comparisons suffer from unknown degree of confounding by indication, which can only in part be controlled by statistical methods.

Suicides Among Patients with Schizophrenia

Suicide risk in schizophrenia is as high as in the major mood disorders. According to a recent meta-analysis [10], pooled suicide rate for people with schizophrenia, based on 16 studies, was estimated at 352 (95% c.i. 239–486) per 10^5 person-years. According to this meta-analysis, risk of suicide is twofold (relative risk 2.01) among males compared to females. The lifetime risk of suicide death in patients with schizophrenia is commonly estimated at about 5% [37]. It is also important to note that in many countries like Denmark [38] and Finland [39] suicide mortality of subjects with schizophrenia has declined along with overall suicide mortality. In Finland, during the 30 years between the years 1984 and 2014, standardized mortality ratio for suicides among patients with schizophrenia declined about 40% [39].

However, like in the other severe mental disorders, suicide risk remains remarkably high during hospitalizations and immediately after discharge, particularly during the first weeks. In the Danish national study of inpatient suicides, incidence of suicide per 10^5 patient years was 1666 among males and 864 among females with schizophrenia spectrum disorders [6], declining only after the first month. A similar period of extreme risk is the first post discharge week, during which the incidences are 1809 and 1246, respectively, declining then gradually over time.

A comprehensive meta-analysis [13] examining risk factors associated with suicide death and other suicidal behavior in subjects with schizophrenia found being male, history of attempted suicide, younger age, higher intelligence quotient, poor adherence to treatment, and hopelessness ($P < 0.0001$) to be most consistently associated with suicide. These findings were broadly consistent with findings of an earlier meta-analysis of risk factors for suicide in schizophrenia [40], which also found previous suicide attempts and depressive symptoms of importance. Other clinical risk factors, such as positive and negative symptoms, seemed to be of less importance. However, a recent Nordic study [41] verified importance of comorbid substance use disorders, particularly of multiple substances, for increasing both suicide and overall mortality. Overall, suicides among subjects with schizophrenia seem clustered into young patients facing severe losses due to their incapacitating illness, and a distressing course of illness with multiple acute psychotic recurrences [13, 42], often complicated by substance use.

Suicides in schizophrenia are commonly described as unanticipated. However, suicides in schizophrenia differ little from the other, in terms of preceding communication of intent, but are reportedly less often preceded by presence of precipitating adversity [17, 43, 44].

Does Clozapine Treatment Prevent Suicides Among Subjects with Schizophrenia?

An important consideration also in schizophrenia is the possible preventive role of treatment. Continuous clozapine treatment of schizophrenia patients has been associated with a significantly lower long-term all-cause mortality rate compared to other antipsychotic use. A Nordic register-based study [45] investigated the comparative effectiveness of antipsychotics for the risk of attempted or completed suicide among representative cohorts of patients with schizophrenia in Finland ($n = 61,889$) and Sweden ($n = 29,823$). Compared with no use of antipsychotics, clozapine use was the only antipsychotic consistently associated with a decreased risk of suicidal outcomes. Hazard ratios (HRs) and 95% CIs for attempted or completed suicide were 0.64 in the Finnish cohort and 0.66 in the Swedish cohort. Clozapine was the only antipsychotic associated with decreased risk of attempted or completed suicide among patients with schizophrenia. Thus, its role in suicide prevention needs to be considered, balancing advantages with the need of laboratory monitoring because of risk of agranulocytosis involved.

Discussion

Overall, findings of the available studies on suicide by subjects with severe mental disorders accord in multiple ways. The lifetime risk of suicides in all the three major disorders – depression, bipolar disorder, or schizophrenia – is in representative inpatient cohort studies in the range of 2–8%. Suicide risk is approximately similar

or somewhat higher among patients with schizophrenia or bipolar disorder, of whom possible differences in mortality between type I or II patients remain unknown (Table 1). There are also concordant extraordinarily strong temporal patterns, as suicides cluster into the weeks immediately after admission into a psychiatric hospital and the immediate postdischarge period. However, suicide mortality estimates have been generally available only for psychiatric inpatients, and only recently have studies with data on outpatients emerged. The proportion of psychiatric patients treated exclusively as outpatients varies markedly by diagnosis, forming the vast majority of depressive patients and those with bipolar II disorder, but only a minority of subjects with schizophrenia or type I bipolar disorder. Furthermore, suicide mortality has markedly declined since the 1990s both overall and among psychiatric patients in most but not all countries, nor necessarily in all settings. For many developed countries, large-scale diagnosis-specific data on suicide mortality in severe mental disorders is either not available or not published. An important issue beyond the scope of this review is the overall high mortality and shortened life

Table 1 Summary of main findings of incidence rates and risk factors for suicide death in the three diagnostic groups in psychiatric settings

	Depression	Bipolar disorder	Schizophrenia
Cumulative incidence (95% CI) of suicide death in long-term follow-up ^a	Males 6.67% (5.72–7.78%) Females 3.77% (3.05–4.66%)	Males 7.77% (6.01–10.05%) Females 4.78% (3.48–6.56%)	Males 6.55% (5.85–7.34%) Females 4.91% (4.03–5.98%)
Overall suicide incidence rate (95% CI) per 10 ⁵ person-years ^b	534 (30.4 – 1449)	237 (160–329)	352 (239–486)
Incidence rates per 10 ⁵ patient-years for the first week of inpatient period ^c	Males 5713 Females 1710	Males 2664 Females 855	Males 1666 Females 864
Incidence rate (95% CI) of suicide per 10 ⁵ patient-years during the first month after discharge from a psychiatric hospital ^c	3600 (3390–3800)	1740 (1470–2040)	1470 (1310–1650)
Risk factors for suicide death	Male gender Previous suicide attempts High severity/psychotic features Hopelessness Comorbid substance use disorders	Male gender Previous suicide attempts Family history of suicide Depressive/mixed episodes Comorbid substance use disorders	Male gender Previous suicide attempts Young age Hopelessness Poor adherence Comorbid substance use disorders

^a In Denmark, from Ref. [23]

^d In Sweden, from Ref. [27], converted to incidence rate per 10⁵ person-years

expectancy of subjects with severe mental disorders [46], which also calls for preventive action.

Role of Gender

Suicide mortality is overall markedly higher among males than females [1]. However, the role of gender as a risk factor in psychiatric settings appears less robust than in the general population. The comprehensive meta-analysis of 100 studies of postdischarge suicides by Chung et al. [26] found no marked gender difference. In contrast, the diagnosis-specific studies reviewed [11–13] consistently reported about twofold risk among males. The reason for this discrepancy remains unclear.

In studies of depression, long-term risk of suicide was found higher among males than females, those with preceding suicide attempts, high severity of depression at outset of illness, or concurrent substance abuse at baseline. Although there are few studies investigating risk factors specifically for suicide deaths in bipolar disorder, the risk is consistently about twofold among males. The Finnish national study by Aaltonen et al. [29] was the largest of the depression studies and was large enough to compare potency and prevalence of 13 risk factors between genders. The observed gender differences were found unremarkable, whereas differences in lethal methods were marked, making them the likely explanation for the higher male suicide mortality in mood disorders. The gender difference has been found about twofold also among patients with schizophrenia [13]. Besides differences in choice of lethal methods; in part, this may be explained by higher prevalence of substance use comorbidity among males [36].

Previous Attempts as Indicators of High Risk

A nonfatal suicide attempt is the strongest known indicator of suicide risk. Overall, patients admitted with suicidal ideas or behaviors have about fourfold suicide mortality postdischarge compared with patients admitted for other reasons [28]. Therefore, it is unsurprising that a preceding suicide attempt emerged as a very strong predictor of suicide among patients with mood disorders. The trajectories of higher risk seemed to persist over time. The clinical importance of this highly consistent finding is obvious, as the cumulative incidence of suicides, particularly among males with depression, approached 20% at worst [29]. However, to some extent these findings may be inflated by methodological factors, as information on all lifetime suicide attempts is usually unavailable, and only on those severe enough to result into hospital treatment, or temporally associated with the index hospitalization or the few preceding years is known. Methodological differences between studies in these factors are also likely to explain differences in observed findings. Since use of violent methods at index attempt may involve much higher risk of future suicide death than overdoses [47, 48], future studies should also examine risk based on the method used in the preceding nonfatal attempts.

Role of Illness Severity

Risk of suicide in severe mental disorders is likely related to severity of illness, but this is often difficult to investigate in the large-scale studies reviewed. In longitudinal studies of depression, patients with severe or psychotic illness at index hospitalization have had higher suicide mortality than those with moderate depression [22], and this higher risk appears to persist for years or even decades. This is true even though severity of subsequent episodes or state of illness at the time of death remains unknown. However, psychological autopsy studies of patients with depression generally find suicides to occur at a time when a depressive episode is ongoing, and clinical studies of suicide attempts among depressive patients find suicidal acts to cluster in illness episodes [31]. It is therefore likely, although uncertain, that suicides among inpatients treated earlier for depression occur during depressive episodes. Patients with psychotic features have highest risk for suicide among those with depression, but whether this is due to the higher severity of depressive symptoms overall, or psychotic features per se, remains unclear. Role of psychotic features for suicide risk in bipolar disorders has also remained unclear, in part because they may be present in mania as well as in depression or mixed states, and imprecise reporting does not allow differentiating these situations. Among patients with schizophrenia, the aspects of severity most strongly associated with suicides are early onset and recurrent exacerbations with prominent psychotic and affective symptoms [13].

Limitations of the Available Studies

The studies reviewed in this chapter comprise comprehensive systematic reviews and meta-analyses, plus large-scale, often national register-based studies. Besides obvious strengths, there are important limitations. Most studies reviewed comprise inpatient populations and therefore represent only the most severely ill patient populations. Thus, rates of suicide are likely to be overestimate rates compared with outpatient settings. In most of the longitudinal studies, data on individuals' characteristics is collected from the life situation at the time of study baseline, whereas situation at the time of suicide at the time of death remains unknown. Some paradoxical findings of higher income, education, or being married and employed as predictors for suicide among psychiatric patients longitudinal studies are likely explained by later losses, which remain unknown in studies relying on predictors at intake [42].

The crudeness of register-based data is revealed by comparing it with comprehensive clinical-epidemiological studies based on careful clinical evaluation. For example, the reported rates of psychiatric comorbidity among patients with mood disorders are minimal in register data compared with clinical cohorts based on structured interviews [22, 49]. Since information on longitudinal course of illness after study intake is usually totally missing, the remarkably strong relationship of clinical state, i.e., presence or absence of illness episodes with suicidal acts [35]

remains only indirectly observed from the temporal association of suicides with hospitalizations. Moreover, register-based studies usually cover only a few of the tens of putative risk factors, with few exceptions [25, 33]. Currently available register-based and other large-scale studies are important in providing epidemiologically credible estimates of total suicide risk over time among those most ill, and of some risk factors. However, they do not represent a complete picture of the numerous factors influencing suicide risk.

It is unavoidable that long-term follow-up studies inform about past decades rather than current conditions. However, there is also a significant delay in reporting findings and updating the literature, and a great need to move toward more real-time monitoring. As there have been significant temporal trends in overall suicide mortality in multiple countries, the suicide mortality estimates reported here may exceed current realities. Whether or not suicide rates and the architecture of risk factors have changed over time is an important future research topic.

Future Prospects of Research

Health care records and registers have been undergoing transformation. Quality registers [33] and electronic health care records [33, 50] may contain an order of magnitude of wider source of data, if available for research. This may markedly advance research on suicides. More sophisticated machine learning tools may also be helpful in uncovering patterns related to risk. However, statistical rarity of suicide will remain a challenge also for future studies, and therefore necessitate large scale data in research. It is to be hoped that availability of such data and methods will advance efforts to prevent suicides among patients suffering from severe mental disorders.

isolation at work, the natural selection of high-risk people to certain occupations, and socioeconomic forces. Physicians and other healthcare workers are considered a high-risk suicide group, and suicide risk seems to be higher for male and female physicians than the general population. Beyond that, the suicide risk appears to be present throughout the entire medical career. The aim of this chapter is to review the epidemiology of suicidality in physicians, risk factors related to suicidal behavior in physicians, suicide risk assessment, and suicide prevention.

Introduction

Completed suicide is among the leading causes of death worldwide. Globally, it accounts for more annual deaths than natural disasters, violence inflicted by others, war, and conflict combined [1]. In 2016, completed suicide caused almost 800,000 deaths worldwide, down from nearly 850,000 completed suicide deaths in 2004 [1]. In 2016, the age-standardized completed suicide rates were 10.53 per 100,000 persons globally [1], and overall, completed suicides accounted for 1.4% of premature deaths worldwide. During the second and third decades of life, completed suicide is the second leading cause of death, representing an economic burden to society [2].

There is considerable inter- and intra-country variability in completed suicide rates, with as much as a ten-fold difference between regions, which correlates with economic status and cultural differences [3]. Moreover, a review of 114 studies deduced that the higher the quality of single studies, the higher the reported suicide rate [2].

The World Mental Health (WMH) Survey Initiative, a study that used data from the World Health Organization (WHO), found that being female, younger, less educated, unmarried, and having a mental disorder were consistent cross-national risk factors for suicidal behaviors [4]. Suicidal behavior is not restricted to fatal suicidal acts, but also includes parasuicide [5]. The suicidal process comprises suicidal behavior as a continuum of gradually increasing seriousness: feelings that life is not worth living, thoughts of taking one's life, seriously considering suicide, suicidal planning, suicidal attempt, and completed suicide [6]. Suicide attempts are up to 30 times more common than completed suicides; however, they are essential predictors of repeated suicide attempts and completed suicides [7].

High occupational completed suicide rates are often linked to factors such as easy access to a method of suicide, which could influence the way chosen [8], social isolation at work [9], the natural selection of high-risk people to certain occupations [10], and socioeconomic forces [11]. Efforts aimed at identifying those occupations at risk and implementing prevention and treatment are hindered by a non-cohesive framework for understanding suicide risk [12].

Physicians and other healthcare workers, such as nurses, were considered high-risk suicide groups in different countries [1, 13, 14]. Both professional status and employment were more critical for men healthcare workers than for women [15]. For instance, one study (1961–1985) in Sweden suggested that suicide risk was higher for male and female physicians, and females (not males) in healthcare jobs, which required lower education, had a lower suicide risk [15]. Even though physicians' completed suicide rate is higher than in the general population, the rate of nonfatal suicidal acts is not [4, 16]. This data supports the hypothesis that physicians do not look for help, but are inclined to act out their suicidal impulses [17].

A 2002 Consensus Statement from specialists invited by The American Foundation for Suicide Prevention to evaluate and devise recommendations for the treatment of depression and the prevention of suicide in physicians established that physicians' suicide neglect sharply contrasts with physicians' heightened attention to smoking-related mortality [18]. Physicians' mortality rates from smoking-related cancer, heart disease, and stroke reduced 40% to 60% from the 1960s [18]. Physicians already face lower mortality risks for cancer and heart diseases than the general population; however, the suicide risk is currently higher [1, 13, 14, 18, 19].

In the next lines, there is an attempt to review the following topics: further epidemiology of suicidality in physicians, risk factors related to suicidal behavior in physicians, suicide risk assessment, and suicide prevention.

Suicide Risk Assessment

Overall Perspective

Tyssen et al. (2004) examined a nationwide representative sample of Norwegian medical students prospectively initially during their final term of medical school (T1), secondly at the end of the first postgraduate (internship) year (T2), and finally in their third (T3) or fourth (T4) postgraduate year [6]. They found a relatively high prevalence rate of 6.4% of postgraduate suicidal planning (T1), in comparison to two previous US studies, whose 1-year prevalence of suicidal planning was 2.8% [20] and 3.9% [21]. Moreover, in an earlier study (2001) of the same group, the lifetime prevalence of suicidal planning at the same T1 was 8% [22], an even higher prevalence than that found in 2004, suggesting the enduring nature of this problem in the medical profession [6]. Accordingly, 9 of the 13 reported suicidal planning remained both at T2 and T3, demonstrating the persistence of suicidal behavior [6]. Common predictors for postgraduate suicidal planning and transition from suicidal thoughts to suicide planning were severe depressive symptoms and personality traits [6]. Reality weakness, considered in this study, a personality trait, defined by chronic illusions, paranoid features, and problems with identity-insecurity and relations, was the most decisive trait for aggravation in suicidal ideation [6].

Another Norwegian study investigated 1042 physicians about suicidal thoughts and attempts and found a lifetime prevalence of serious suicidal thoughts of 10% [16]. The main risk factors were being a woman, living alone, and depressive

symptoms. However, in this study, personality traits did not relate to suicidal thoughts [17].

According to Braquehais et al. (2016), who examined 493 medical records of physicians and nurses admitted to an inpatient unit, patients with a recent suicide attempt (RSA) attempted suicide more frequently when compared to patients without an RSA (OR = 11.364; 95% CI = 5.361–24.086) [23]. RSA physicians were younger than those without an attempt, but their age was similar to that observed in completed suicide [23]. Concerning the primary diagnosis at admission, unipolar affective disorders and cluster B and C personality disorders were predictors of suicide attempts [23]. This study's main limitation was the small sample size ($N = 36$), which restrains the conclusions [23]. Recently, a meta-analysis about suicide among physicians and healthcare workers stratified its results and meta-analyzed five studies to find the number of physicians who had attempted suicide among all the physicians. They also meta-analyzed seven studies to investigate the number of physicians with suicidal ideation among all the physicians [13]. The authors found that the prevalence of physicians who attempted suicide among all the physicians was significant (0.01, 95CI 0.01, 0.02; $p < 0.001$), as the prevalence of physicians with suicidal ideation among all the physicians (0.17, 95CI 0.12, 0.21; $p < 0.001$) [13]. One significant aspect to observe while analyzing physicians' completed suicide studies concerns the epidemiologic measures of differential mortality risks. The Standardized Mortality Ratio (SMR) of physicians stands for age-standardized suicide mortality ratio, the ratio of observed (O) and expected (E) suicide deaths as follows: $SMR = O/E$, where O equals total physician suicides/total physician population, and E equals total population suicides/total population (using the same sex, age groups, locations, and year ranges) [1, 24]. The Proportionate Mortality Ratio (PMR) of physicians indicates the ratio of the physician suicide proportionate mortality (i.e., physician suicide/physician all-cause mortality) to that of the general population suicides (i.e., general population suicide/general population all-cause mortality) [1, 24]. Because the PMR is a ratio comparing proportionate mortality in physicians vs. that of the general population, it can be harder to interpret the SMR as the all-cause mortality influences the SMR. Also, in the SMR, the denominator of observed and expected suicides is the same number (100,000 population of physicians or general population). Thus, the PMR is typically calculated when there is insufficient data for the SMR. The SMR and the PMR are therefore useful for different reasons; for example, policymakers might care more about the effects of a particular occupation on suicide compared to the general population, while others might wonder how suicides compare to other causes of mortality within a specific occupational group [1, 24]. For a population-based study, the SMR might be more valuable as it depicts the number of deaths per 100,000 in a given population, adjusted by age in a given year. This health indicator shows the real impact of physician suicides and is less influenced by other causes of mortality [1, 24]. Finally, despite not being a comprehensive study of all physicians' completed suicides, but a gender sub-analysis, a scanning from an England dataset made it possible to obtain the SMR and the PMR for comparison during the same interval (2011–2015). This was essential to highlight the differences between the two

measures. The suicide PMR was high for male physicians (1.85 [95%CI: 1.41–2.38]) and higher for female physicians (1.97 [95% CI: 1.23–2.98]), which was significant in both cases despite the much lower and nonsignificant risks suggested by their suicide SMRs (0.63 [95%CI: 0.43–2.28] and 1.01 [95%CI: 0.44–2.31] for male and female physicians, respectively [1]. The limited PMR data suggests that out of all causes of death in physicians, suicide is an important one. However, physicians are not as protected from suicide as they are protected from other causes of mortality [1].

The meta-analysis by Schernhammer and Colditz [14] included mostly SMR but also PMR data [14]. Duarte et al. [1] adopted the same procedure, despite preferring the SMRs for the meta-analysis. They were striving for better consistency and the understanding of the results concerning their aim: to compare male and female suicide risks with those of the general population [1]. They found that the male physicians' SMR was significantly lower than the SMR of the general male population (0.67 [95% CI, 0.55–0.79], while the female physicians' SMR was considerably higher than the SMR of the general female population (1.46 [95% CI, 1.02–1.91]) [1]. A cumulative meta-analysis revealed that the male physician SMR still decreased, but with greater precision (effect sizes from 0.58 [95% CI, –0.20 to 1.36] to 0.67 [95% CI, 0.56–0.78]). Female physicians showed an early increase (effect sizes from 0.62 [95% CI, –0.23 to 1.47] to 1.76 [95% CI, 1.34–2.18]), followed by a trend toward decreasing suicide risk (effect size, 1.43 [95%CI, 1.12–1.73]), that was still high compared to women in the general population [1]. Duarte et al. [1] also showcased the PMR data from the US National Occupational Mortality database (NOMS) as a critical demonstrator of the trends (1985–1998 dataset to the 1999–2003, 2004–2007, 2013 dataset) from the differences by sex and race in physicians' suicide [1] (addressed below in risk factors).

Crude completed suicide rates for both men and women decreased between 2000 and 2016 in Europe and all World Health Organization regions other than the Americas [1]. To better understand whether the SMR changes over time (before and after 1980) were driven by observed suicide rates in physicians (male and female) or by expected suicide rates in men and women of the general population, Duarte et al. [1] performed a meta-regression and found different patterns [1]. The meta-regression results assessing the association of time with (i) expected suicide rates in the general population and (ii) observed suicide rates in male physicians, showed a decrease in suicides after 1980, but this was only significant in male physicians ($\beta = -35.37$ [95% CI, –62.33 to –8.41]; $P = 0.01$), and time explained 20.21% of the variance. Meanwhile, the results were nonsignificant in each of the meta-regressions for expected suicide rates among women in the general population) and observed suicide rates in female physicians [1].

A similar pattern was lately reproduced by a recent meta-analysis and systematic review about physicians suicidality [13]. This review evidenced an overall time effect on completed suicide SMRs (–0.15; 95CI –0.29, –0.01; $P = 0.032$), which signify that the risk decreased over time. This relationship was significant in Europe (–0.18; 95CI –0.37, –0.01; $P = 0.044$), but not in the USA (–0.11; 95CI –0.37, 0.15; $P = 0.370$) or in Australia, New-Zeeland, and Pacific (–0.48; 95CI –0.09,

7.12; $P = 0.570$) [13]. It also found an elevated physicians' completed suicide SMR (overall; male and female) to general population of 1.44 (95CI 1.16, 1.72), despite an important heterogeneity ($I^2 = 93.9\%$), and with some countries showing higher risks [13]. The SMR was 1.27 (95CI 1.05, 1.49; $P < 0.001$; $I^2 = 71.3\%$) in Europe, 1.63 (95CI 1.29, 1.96; $P < 0.001$; $I^2 = 74.1\%$) in North America, 0.79 (95CI 0.03, 1.62; $P = 0.002$; $I^2 = 79.5\%$) in Australia, New-Zeeland, and the Pacific, and 1.26 (95CI 0.56, 1.96) in Africa [13]. Meta-regressions demonstrated a higher risk of suicide in North America than in Australia, New-Zeeland, and the Pacific (0.92; 95CI 0.22, 1.63; $P = 0.013$), and especially higher in the USA vs. the rest of the world (1.34; 95CI 1.28, 1.55; $P < 0.001$) [13].

General Hypothesis and Specific Risk Factors for Completed Suicide

Cornette and colleagues [26] initially suggested the possibility of using the interpersonal psychological theory of suicidal behavior (IPTs) [25] to understand suicide in physicians [12, 25]. The components of the IPTs are burdensomeness, thwarted belongingness, and acquired capability for suicide. This theory postulates perceived burdensomeness as a miscalculation made by an individual who feels that their death would be of more benefit to others than their life. Thwarted belongingness would be a profound sense of isolation from others. Finally, acquired capability for suicide is the physical capacity to inflict severe self-injury and is hypothesized to result from continued exposure to painful or provocative events [25, 26]. Medical trainees and physicians experience feelings of burden in the circumstances such as academic failure and burnout, financial debt, mental illness, feeling excessively responsible for the patients' issues, and inter-role disagreement [26]. Failure in interpersonal belongingness might arise from difficulty accessing various sources, such as family, friends, coworkers, and a team (e.g., sports) or group (e.g., medical trainees). Studies suggest that the medical training environment may not be supportive, and seeking professional help is considered by the students, potentially stigmatizing and harmful to their future careers. Thus, students are more prone to talk to their peers since they could better empathize with their issues [26]. For students, who were inclined to seek professional help provided by their medical school, there was a lack of knowledge about both university and nonuniversity-related services in the area [26]. Medical training accustoms individuals to be less emotionally reactive to injury and death. This could facilitate self-harm and suicide attempts in individuals who are not coping with stress [26].

Moreover, medical trainees know the dosing and effects of lethal medications, an expertise that is unknown by the general population [26]. Fink-Miller (2015) studied a sample of 419 physicians and examined the components of the IPTs and their relationship to suicidal behavior. He demonstrated that perceived burdensomeness predicted suicidal ideation, while thwarted belongingness was a predictor of prior suicide attempts [27]. Furthermore, first attempt suicide physicians displayed the same capability of those who had attempted suicide previously. Being a physician is part of a population that shows high capacity for suicide [12, 28]. A follow-up study assessed provocative experiences that physicians commonly encounter at work (e.g., withdrawing life support, witnessing a patient's death) to determine whether these

events' frequency predicted capability for suicide [29]. Results indicated that provocative work experiences predicted scores on ability, even while controlling for painful and provocative experiences outside the workplace. These findings ultimately suggest that physicians' idiosyncratic occupational experiences could increase their suicide [29].

Suicide risk factors already well established for completed suicide in the general population were also related in physicians' data: mental disorders [29–32] and civil status/relationship problems [30–33]. Other less common factors in the general population analysis found in the physicians' studies were employment status (31,336) and access to the means of suicide [36].

Psychiatric Diseases Risk Factors

Depression is the leading cause of death by suicide worldwide and is number two in years lived with disability (globally up to 11%) [7]. Medical practitioners at all stages of their careers have higher depression levels than the general population [37]. A series of recent meta-analyses estimates the prevalence of depression to be 27% in medical students [38] and 29% in resident physicians [39]. The investigation of depression in primary care settings can be addressed by questioning about anhedonia and depressed mood. They are usually accepted as a sensitive and specific screening measure [40]. A Canadian survey examined 3213 physicians and found that 23.2% reported feeling “sad, blue, or depressed for two weeks or more in a row” during the 12 months before the survey. Female physicians were more likely depressed (28.6%) than male physicians (20.4%; $P < 0.001$) [40]. Moreover, 20.8% declared having had anhedonia for 2 weeks (22.7% of women and 19.8% of men, whose difference was not statistically significant). As expected, depression was significantly related to anhedonia ($P < 0.001$); however, this association was not absolute [40].

To investigate factors associated with suicide in physicians, Hawton et al. (2004) conducted a psychological autopsy of 38 suicide cases of working doctors. They found that 86.2% had psychiatric disorders, with depression being the most common one, followed by drug or alcohol abuse [41]. Other group found that the three most common psychiatric disorders among physicians who committed suicide were depression, drug dependence, and alcoholism [5]. Moreover, studies analyzing physicians' blood samples regarding the presence of antidepressants demonstrate that physicians are undertreated for depression, despite current effective treatments [1, 19].

Among the individuals who completed suicide, having a mental disorder was associated with a higher odds of being a physician (OR: 1.34, CI: 1.01–1.82, $P = 0.045$) [19]. Nevertheless, logistic regression analysis using backward stepwise elimination found that the mental disorder dropped out of the final model given potential multicollinearity among the predictors ($P = 0.054$). Recently, in a meta-analysis by Duarte et al. [1], there was a positive association between previous or current mental disorders and physicians' suicide risk in all studies included in this meta-analysis [30–33].

Sex Risk Factor

Two previous reviews evidenced the difficulty in establishing the physicians' sex with higher suicidal risk [14, 42]. Lindeman et al. (1996) showed that both sexes

conferred higher suicidal risk for physicians than the general population. The completed suicide rate of female physicians, even after adjustment, would be close to that of their male counterparts [42]. These findings were replicated by Schernhammer et al. (2004) (male: 1.41; 95% CI: 1.21–1.65/female: 2.27; 95% CI = 1.90–2.73); however, they draw attention to data revealing randomness for men, but some indication of publication bias for women, since data on female physicians' suicides are still few [14].

More recently, a published systematic review and meta-analysis by Duarte et al. [1] about age-standardized suicide mortality ratios for female and male physicians from 1980 to the present moment showed differences in physicians' sex suicide over time [1]. There were significantly higher physician completed suicide rates for women compared to women in the general population (SMR of 1.46 [95% CI 1.02 to 1.91]). However, male physician completed suicides were no longer significantly greater than men-age-adjusted suicide mortality ratios (SMR of 0.67 [95% CI 0.55 to 0.79]). Therefore, Duarte et al. [1] SMRs remained high for female physicians but became lower for male physicians when compared Schernhammer and Colditz [1, 14]. Moreover, meta-regression suggested that the decrease in male physician suicide SMRs overtime was driven by the physicians rather than the population completed suicide rates [1]. Male physicians' relatively protection from workforce/unemployment factors affecting men of lower socioeconomic status may have obscured any burnout-related effects.

Conversely, the same claim could not be made for female physicians vs. females in the general population, potentially because the pre-1980 data was underpowered [1]. Nevertheless, while decreasing, the SMR for female physicians was still high, implying that more excellent female representation in the physician workforce may not have overcome the magnitude of their increased risk than women in the general population [1]. Moreover, family demands, frustration, and career dissatisfaction could be a crucial factor explaining higher risk in female physicians [43, 44]. Besides, the well-known risk association between suicide and mental disorders could render female doctors higher suicidality because of their higher morbid risk for primary affective disorders [45]. Among male physicians, the excess of completed suicides may also reflect depression induced by a sense of failure to achieve early goals, missed opportunities, and constricting potential for the future [44].

Finally, internal characteristics should also be taken into account while analyzing these results. In Kőlves and De Leo (2013), the same female medical doctors had significantly higher completed suicide rates when compared to education professionals (RR: 3.88; 95% CI: 1.54–9.34), but not when the general female population was used for comparison (RR: 1.74; 95% CI: 0.76–3.78) [32]. Lindeman et al. (1997) evidenced a similar behavior; while comparison between male physicians and other male professionals had an SMR of 2.4 (95% CI: 1.7–3.3), male physicians and the general population had an SMR of 0.9 (95% CI: 0.6–1.2) [43].

Race and Ethnicity Risk Factor

Studies suggest that race could be a covariate in physicians' suicidality epidemiology. In the United States, data suggests that while US black men had improvements

in both suicide and all-cause mortality between the time-periods (1985–1998; 1999, 2003–2004, 2007–2013) [1, 24]; black male physicians either had a spike in suicide rates or a sharper drop in all-cause mortality than the rest of the black male population, or both [1, 24]. Conversely, suicide risk appears lower in white male physicians than white men in general [1, 24]. For white female physicians, there was a slight drop from 2.66 to 2.42 (higher than white male physician PMRs in either case), while black female physicians' suicide PMRs were unavailable.

The place of birth of a physician was relevant to suicide mortality rates in unpublished data that established that young people from overseas had a significantly higher mortality rate from suicide than those born in the British Isles [44].

Age Risk Factor

Petersen and Burnett (2008) demonstrated that as male physicians get older, there is a tendency for them to have a significantly higher suicide risk than the general population [47]. Besides, using the general population as control may inevitably lead to significant differences between physicians and the general population, especially if the general population predominant age is inside the age group less likely to commit suicide [48, 49].

An epidemiological study by Gold (2013) that used data from the United States National Violent Death Reporting System to evaluate demographics, mental health variables, recent stressors, and suicide methods among nonphysician versus physician suicide victims in 17 US states evidenced that being older was a risk factor for the latter [1, 19]. Of the 31,636 US adult suicides, physicians were older than nonphysicians (mean age 59 vs. 47 years, respectively; OR: 1.04, CI: 1.03–1.05, $P < 0.0005$) [19]. Nevertheless, US suicide rates rise rapidly up to age 24, and it is unlikely for medical students to have finished their professional training by the age of 24. Therefore, it would be impossible to identify physicians among the deaths of younger individuals [19]. Ultimately, Duarte et al. [1] evidenced that global suicide rates were higher between 15 and 59 years old than 60 and older, while the physician suicide risk was higher at age 55 and older [1].

Medical Specialty Risk Factor

The majority of studies, which looked upon a conferred suicidal risk accordingly to medical specialty, found specialties with a higher risk than others [16, 34, 43, 46, 50–52], but with contradictory findings. For instance, anesthetists could be those with a greater suicidal risk [46, 51–53]; however, in Carpenter et al. (1997) [50] and Lindeman et al. (1997) [43], they were exceeded by psychiatrists. Moreover, whereas in Carpenter et al. (1997) [50], general surgeons were significantly less prone to suicide, in Arnetz et al. [16] they were diametrically more prone. Nevertheless, Dutheil et al. [13] seem to have a more definitive answer concerning this issue. In their review, the percentage of suicide in general practitioners was 32% (95CI 21, 43; $P < 0.001$; I₂ = 93.1%), while in internal medicine it reached 16% (95CI 9, 23; $P < 0.001$; I₂ = 88.6%). Among psychiatrists, the percentage of suicide was 11% (95CI 9, 14; $P = 0.30$; I₂ = 17.5%), followed by 4% in surgeons (95CI 2, 5; $P < 0.001$; I₂ = 62.8%), 3% in other medical specialties (95CI 3, 4; $P = 0.02$;

I2 = 40.7%), and 2% in internships (95CI 1, 4) [13]. Meta-regressions demonstrated a higher risk of suicide in general practitioners than internal medicine (0.12; 95CI 0.05, 0.19; $P = 0.001$), than psychiatrists (0.17; 95CI 0.09, 0.24; $P < 0.001$), other medical specialties (0.24; 95CI 0.18, 0.30; $P < 0.001$), surgeons (0.25; 95CI 0.19, 0.30; $P < 0.001$), and internships (0.24; 95CI 0.15, 0.34; $P < 0.001$) [13]. Moreover, a higher risk of suicide was found in internal medicine than in other medical specialties (0.12; 95CI 0.08, 0.17; $P < 0.001$), surgeons (0.13; 95CI 0.08, 0.18; $P < 0.001$), and internships (0.13; 95CI 0.03, 0.22; $P = 0.008$) [13]. Finally, there was a higher risk of suicide in psychiatrists than other medical specialties (0.07; 95CI 0.02, 0.13; $P = 0.009$) and surgeons (0.08; 95CI 0.02, 0.13; $P = 0.005$) [13].

Easy access to potentially lethal drugs, a high prevalence of burnout, increased workload with fear of harming patients, the organizational burden with low autonomy, and conflicts with colleagues could render a higher risk of suicides in anesthesiologists [13, 36, 51, 54]. Half of the anesthesiologists who committed suicide chose an anesthetic agent for these acts [36]. On the other hand, psychiatrists, who self-poisoned, did not use any psychotropic medication [36]. This might reflect that psychiatrists rarely have direct contact with the drugs they prescribe. They may be aware that many psychotropic agents are less dangerous in overdose than other medications [36]. Stressful and traumatic experiences such as, paradoxically, dealing with suicides of the patients, seem much more related to a higher risk of psychiatrist's suicide [13].

Civil Status Risk Factor

Young married couples seem to have an increased suicide risk, with some studies suggesting that marriage can be protective for men but not for women [19]. This gender influence on marital status and suicide risk could also be real for physicians. Moreover, data from patients with a psychiatric hospitalization demonstrate that having a high income, employment, postgraduate education, and being married raises suicide risk [19]. Physicians have much lower rates of divorce than the general working population and are more likely to be married at the time of death [19]. Therefore, civil status could influence suicide risk, especially in young female physicians. They could have a higher completed suicide risk than their male counterparts and the general population.

A study tried to disentangle this question by performing a multivariate logistic regression analysis of national mortality data from the US Public Health regarding the independent variable marital status. It found that after controlling for marital status, the odds ratio for physicians' suicide were: divorced: OR 1.46, $P < 0.05$; widowed: OR 1.54, $P < 0.05$; single: OR 0.82, $P < 0.05$ [35]. In conclusion, these findings demonstrate that marriage can have a protective effect. Because other studies did not control for marital status among physicians, they could have underestimated the incidence of suicide in this population [35].

Research addressing the physician's family suicide rates would also be of interest since physicians' wives seem to have a higher risk of suicide than the general population wives [55].

Career Risk Factor

Suicidality in physicians could have its geneses in the student years or even earlier [22, 38, 56]. A 2016 meta-analysis that assessed depressive symptoms before and

during medical school ($n = 2432$) showed a 13.5% (range, 0.6% to 35.3%) median absolute increase in depressive symptoms [38]. With a crude prevalence of suicidal ideation of 11.1% (2043/21002 individuals; 95% CI, 9.0% to 13.7%, $I^2 = 95.8\%$) [38].

Appreciated qualities in the workplace like perfectionism, obsessive attention to detail, an exaggerated sense of duty, an inflated sense of responsibility, the desire to please everyone, increased stress, and depression [57] imprison physicians in a vicious circle [7, 13, 33, 58].

Research suggests that most physicians commonly use self-prescribed drugs and self-treatment when faced with medical illness and psychological distress [1, 6, 59]. Additionally, retrospective toxicology screening of suicide data finds that physicians were at significantly higher odds than the nonphysicians of having antipsychotics (OR: 28.7, CI: 7.94–103.9, $P < 0.0005$), benzodiazepines (OR: 21.0, CI: 11.4–38.6, $P < 0.0005$), or barbiturates (OR: 39.5, CI: 15.8–99.0, $P < 0.0005$) present on toxicological tests. There was no significant difference concerning antidepressants, opiates, amphetamines, or cocaine and physicians were less likely to have a blood-alcohol level above 0.08% [19]. These positive toxicology findings may indicate substance abuse, self-medication, or intentional abuse [1].

Physicians referred for fitness for duty evaluations showed a completed suicide rate of 3.5%, a number 175 times higher than those in the general population [33]. Being found unfit to practice, in solo practice, and the chronic use of benzodiazepines was associated with physicians' suicidal behaviors [33]. A more recent study in the UK showed that, despite being under GMC (General Medical Council) investigation (2010–2013), only 4.8% of the complaints led to warnings/sanctions. However, defensive practice augmented, and 82–89% of the physicians become overcautious, while 46–50% adopted an avoidance posture, avoiding complicated patients and procedures [58]. Furthermore, nearly a quarter of the deaths in physicians evaluated for fitness to practice by the GMC (2005–2013) were due to suicide ($n = 24$) or suspected suicide ($n = 4$) [22, 58, 59]. The investigation itself was associated with suicidal ideation (15% of physicians), moderate-severe depression (>26%), and moderate-severe anxiety (22%) [58].

A survey showed that physicians' satisfaction declined over the last 10 years in the USA, which was related to lesser time spent with the patient and their private life [13]. US physicians might also be particularly stressed by medical errors, which are the third most important cause of death, leading to a more defensive practice [13]. Indeed, job-related problems are 3.12 times more likely to predict suicides in physicians vs. nonphysicians. Physicians' job satisfaction might be an intermediary in "a causal pathway between depression and suicide" [24, 61]. Making decisions about life and death, and being always in the vicinity of seriously ill people may exert severe pressure, challenging to cope with [15]. Work-related stress was associated with physician suicide [35], as anticipated when physicians retire, if all else remains equal, their relative risk of suicide should diminish [35].

The already mentioned 25 years study (1979–1995) in England and Wales that analyzed death entry data of physicians who died by suicide or undetermined cause, compared methods used for suicide by physicians with those used by the general population. Methods used were analyzed according to sex, occupational

status, and medical specialty, to undercover if access to dangerous means influenced the pattern of suicide. Self-poisoning with drugs was more common in physicians than in the general population suicides (57% vs. 26.6%; OR = 3.65, 95% CI 2.85–4.68); including the retired physicians. The excess of self-poisoning deaths was more pronounced in males than females, although self-poisoning was generally more common in females, both in physicians and the general population [36]. Self-poisoning was somewhat, but not significantly, more frequent in female physician doctors than the male counterparts [36]. Finally, a systematic review showed that countries with lower firearm prevalence (e.g., in Western Europe) had fewer firearm suicide deaths when physicians' suicide was examined [1]. Furthermore, suicide methods may also vary inside countries and follow the same pattern: physicians in states with high firearm prevalence seem to die of suicide by firearm more than physicians in states with lower firearms prevalence (e.g., California) [1].

Burn-Out

Physicians are exposed to various stressors related to medicine judicialization and organization oversight that go beyond the complexity of diseases and clinical cases [61]. The interaction of medicine judicialization and organization (e.g., federal/state levels, medical boards/oversight agencies, etc.) harms physicians' and patients' health [61]. A NEJM Catalyst survey highlights the disconnection between healthcare executives and clinicians [61]. It suggests that physicians tend to experience systematic factors that they do not directly have control, such as documentation/clerical work as having the most significant impact on burnout [61]. On reviewing the National Academy of Medicine Action Collaborative on Clinician Well-Being and Resilience Reference Collection, a recurrent association was found between burnout and the lack of social connectedness [61]. Burnout affects 50% of physicians, who are mostly working in emergency medicine, a scenario that has been compared to warzone [61]. Burnout was twice as prevalent among physicians as US workers in other fields, after controlling for work hours and other factors [62]. Between 2011 and 2014, the prevalence of burnout increased by 9% among physicians, while remaining stable in other US workers [62]. Several studies have also found a high prevalence of burnout and depression among medical students and residents, with rates higher than those of age-similar individuals pursuing other careers [62]. Cross-sectional studies of physicians demonstrated that burnout is independently associated with 25% increased odds of alcohol abuse/dependence and 200% increased odds of suicidal ideation among physicians [62]. In a longitudinal study of medical students, burnout predicted the development of suicidal thoughts over the ensuing year, independent of depression [62].

High clinical workload raises the risk of malpractice since there is little time to establish an excellent physician-patient relationship and optimal clinical care [61]. Malpractice risk also increases by age and male sex (both suicide risk factors) [61]. Yet, specialties at the highest risk of paid claims, mostly surgical specialties, do not have high suicide rates. On the contrary, the specialties psychiatry and anesthesiology, which produce less in claims, have higher suicide rates [61].

Suicide Prevention

Despite the questionable effect, physicians get used to coping with their stress or psychologic problems with denial and avoidance [6, 63]. It seems that physicians fear that their need for help may indicate weakness or inability to cope [63]. Moreover, they have concerns about confidentiality [59]. These doctors' attitudes denote a perceived stigma by those who should not, and impede their access to appropriate healthcare [63]. Even if a physician had consulted a colleague within the past 3 years, 76% still self-treated [7]. Approximately one-quarter of physicians reported mental health concerns, which interfered in their handle with their workload at least some of the time in the past month (26.5%), and disagreed having a balance of work and nonwork activities (24.5%).

Additionally, one out of seven physicians reported not knowing of resources they would feel comfortable using if they needed help for a mental health problem (14.5%). The presence of either depression or anhedonia was significantly related to all three findings above ($P < 0.001$). A logistic regression examining not knowing of mental health resources as the outcome and three predictors – (1) sex, (2) specialty (dummy coded to examine: general practitioners/family physicians vs. psychiatrists vs. anesthesiologists and other specialists), and (3) practice type (solo vs. group or different practice settings) revealed that the first two, sex and specialty, were independently significant predictors [40].

Furthermore, considering the stress-vulnerability model, where vulnerability traits due to several factors (such as psychiatric comorbidities, history of suicide attempt, childhood-maltreatment) overlap with environmental stress [1, 24, 61], physician suicide prevention may need a multilevel approach. The preventive approach may consist of screening, assessment, referral, and education and destigmatizing help-seeking by at-risk medical students/physicians [13]. Vulnerability traits should be recognized early in training by parties not involved in the institution, medical regulation, and legislature. If this information is protected even from subpoenas, then vulnerable students and physicians can be given support and resiliency training early on and maintain a support network throughout their careers [1, 24, 61]. A review of the literature on stress management programs for medical trainees demonstrated that participants showed decreases in depression and anxiety and greater use of positive coping skills. Moreover, they resolved their conflicts remarkably and improved immunologic functioning, enhanced knowledge of the effects of stress, and other beneficial effects [40]. In New Zealand, the Medical Protection Society and Medical Assurance Society jointly funded a counseling service for physicians with work-related stress or impairment. An evaluation of the program revealed that participating physicians valued confidentiality, choice, and independence of the provider and believed that the service contributed to them remaining in or returning to work; and identified a need for more significant publicity about the service [40].

Therefore, barriers to physicians' access to proper healthcare should be the first aspect addressed while preventing their suicide. Kay et al. (2008), in a systematic review of 26 studies of physicians' healthcare, revealed essential similarities

between doctors and the general population in their health access, especially regarding mental health issues [7].

Despite the low quality of the data, physicians' healthcare access barriers are possibly divided into three categories: related explicitly to the doctor-patient seeking healthcare, predominantly under the control of the provider of the medical care, and within the medical system itself [7].

Patient Barrier

Embarrassment

Up to 71% of doctors described themselves as embarrassed when seeing another doctor, which was more prominent for mental health problems. Besides, many doctors described concern (embarrassment) that they should not impose upon another doctor's time, mostly if the illness were a trivial one [7].

Time and Cost

The lack of time was the single most quoted barrier [7]. Both direct and indirect costs included fees charged, time off, and access to disability and business insurance cover [7].

Personality Traits

Physicians more likely to be under general practice care were those who held a mild belief that a physician could help. However, a physician who had a strong idea that health was under their control were less likely to have general practice assistance [7].

Medical Knowledge

A doctors' reluctance to seek healthcare for minor illness was coupled with a tendency to rationalize symptoms as minor (trivial), which in the end were modulated by having special knowledge in the health field affected [7]. Medical acknowledgment also made doctors more aware of medical care limitations and encouraged skepticism and lack of compliance [7].

Provider Barrier

Confidentiality

Physicians' awareness of confidentiality limitations was another hurdle since the provider sets how to keep confidential information. Moreover, anxiety about confidentiality was greater for physicians with mental health issues [7].

Quality of Care

The quality of care is implemented by the provider; however, there are substantial reports of poor medical care experience, which could reduce the physician-patient's future health access [7].

System Barrier

Structural Issue

The long hours of duty, difficulty accessing locums, the lack of training in accessing appropriate self-care, and how to treat their peers (in formal and informal settings) made it difficult for the doctor to access care [7].

Cultural Issues

Doctors commonly face intense pressure from both medical colleagues and the community to be healthy or control their illness, encouraging self-treatment and corridor consultations. Besides that, about 25% of the physicians hide their illnesses from colleagues [7].

Despite the wide range of the barriers postulated above, in the end, physicians' access to healthcare were more significantly related to systemic (long hours and cultural issues) than individual obstacles [7]. Therefore, the conduction of short automatized mental health screenings and the annual physical examinations and other required health screenings could be an efficient measure to hinder these difficulties [64]. The American Foundation for Suicide Prevention offers an example of an Interactive Screening Program that provides subscribed institutions with access to a customizable software tool to conduct anonymous, confidential, and web-based screenings [64]. Responses are analyzed and triaged, and, if necessary, a counselor facilitates referral for mental health treatment [64]. Incorporating this screening tool into traditional evaluation and referral processes could reduce stigma and allow for service coverage with employee health insurance [64]. It is important to note that mental health treatment may impact the physicians' ability to practice medicine, e.g., medication side effects or cognitive effects of electroconvulsive therapy. Therefore, it is critical managing psychiatric comorbidities in early stages, reducing the need for more extreme treatments [1, 24, 61]. The WHO reports that suicide reduction could benefit from cognitive and problem-solving therapies, intensive care plus outreach, interpersonal psychotherapy, acceptance, and commitment therapy [1, 24, 61].

Since 2000, national prevention strategies have been established in 28 countries. These include primary and secondary preventive strategies in Europe (13 programs), the Americas (8 programs), Western Pacific (5 programs), South-East Asia (2 programs), and Africa and Eastern Mediterranean (0 programs) [2]. For instance, OSPI-Europe intervention is a five-level approach for optimizing and implementing suicide prevention. In level 1, general practitioner physicians were educated and trained using training sessions and videos. In level 2, which consisted of public relations activities, training sessions were made available for multipliers and community facilitators such as priests, social workers, teachers, caregivers, and the media (level 3). In level 4, the target individuals were psychiatric patients and their relatives. They were offered support and self-help groups, emergency cards, and information material. The restriction of lethal means, especially benzodiazepines, was part of level 5 [65]. This restriction was primarily implemented in the local setting and integrated into the preexisting groups because to restrain the access

to lethal means is not possible to carry out without a community-based intervention approach, often requiring national legislation [65].

On the other hand, programs focusing mainly on physicians would be of crucial importance since, as evidenced above, physicians' suicide have intersections and disentanglements with the general population [24, 61]. Even though these strategies are not occupational specific, some physicians' characteristics should receive a more profound look while addressing their suicide prevention. For example, the diminished rate of physicians' suicide in Europe could be associated with a significant reduction over the last decades in physicians' working hours, following official instructions such as the European Working Time Directive (EWTd) [13].

Initiatives like those of the Centers for Disease Control and Prevention, which gathers annual data from hospitals on self-harm-induced nonfatal injuries and collects survey data, are crucial to improving identification of suicide attempts. They are much more prevalent than completed suicide and are the most validated predictor for future suicide attempts [1, 13, 14].

Regarding the lack of global data on physician suicides, it may be particularly helpful to expand existing databases such as the ILO Global Database on Occupational Safety and Health Legislation (LEGOSH), collecting more detailed data on the cause of death, demographics, and occupation [1, 24, 61].

The American Foundation for Suicide Prevention elaborated a consensus for confronting depression and suicide in physicians [18]. It recommends the transformation of professional attitudes and the modification of institutional policies so that physicians would feel encouraged to seek for help. Since physicians' health habits can affect their health and prevention recommendations, becoming aware of their depression and suicidality can increase the recognition and treatment of these mental health problems in patients, colleagues, and medical students [18]. Additionally, as physicians gain experience in caring for their patients' depression and suicidality, they are more inclined to get care for themselves [18]. The investment of time and resources in healthcare teams could increase the clinician's well-being and ameliorate patient outcomes [66]. However, to develop, administer, and maintain high-functioning healthcare teams is a complicated task. Although high-functioning healthcare teams are very heterogeneous, they usually have key features that make them succeed [66]. These are shared team identity, values, aims, leadership, defined roles, routine meetings, competent staff, shared space, psychological security, accessible communication, and reciprocal respect [66]. Furthermore, helping team members virtually, constructively solving conflicts, sharing and shifting functions, coordinating the team, observing, and giving feedback can also contribute to a high-functioning healthcare team [66].

People close to physicians who died of suicide are often unaware of their suffering, possibly due to the physicians' pretense of being well-adjusted, and loved ones usually attribute behavioral changes to work-related stress. Beyond that, some personality factors and the fear of being obligatorily reported as impaired by colleagues may prevent them from seeking help [26]. Joining healthcare teams and being encouraged to communicate openly can destigmatize psychological and work-related vulnerabilities, allowing doctors to ask for professional and personal help [61]. Some initiatives like the Physician Support Line – (+1 888 409-0141)

(a free and confidential support line launched on 30 March 2020) are already connecting American physicians with volunteer psychiatrists [61] and could be replicated across the nations.

Ultimately, most anti-burnout efforts target personal factors (e.g., physician resiliency), not core problems. Burnout is driven by workload and inefficiency, lack of work autonomy and meaning, work-home conflict, negative patient relationships, and clerical tasks [61]. Workplaces should use effective strategies to reduce burnout, such as minimizing clerical duties, redesigning practice, aligning physicians/organizational values, increasing meaningful work, and finally by providing unforced physician resiliency training [61]. Training physicians may benefit from “compagnonnage” and training on dealing with future organizations [61]. Furthermore, complementary strategies on burnout and suicide prevention for physicians should foster social connectedness [61]. In more practical terms, recommendations like those by the General Medical Council investigation (UK) can positively impact reducing burnout. They included reducing health examiner assessments, making physicians feel innocent until proven guilty, having investigational staff exposed to frontline clinical practice, and establishing a National Support Service for physicians [61].

Another practical proposition to tackle burnout would be adopted by the US Federation of State Medical Board (FSMB), which has as policy the Report and Recommendations of the Workgroup on Physician Wellness and Burnout [67]. They recommend that State Medical Boards (SMB) evaluate the necessity to actively question physicians about their mental health, addiction, or substance use. The questions should focus on the current impairment related to the physician’s practice, competence, and ability to provide safe medical treatment to patients. Questions should neither concentrate on the illness/diagnosis nor previous therapies. Moreover, physicians currently in treatment for mental health problems or addiction can apply for licensure or license renewal without disclosing their diagnosis/treatment to the board. Information about their treatment should not be publicly disclosed. Beyond that, SMB should highlight the physician’s treatment importance by making available options for treatment and other resources. About the disciplinary undertaking, SMB should explain that it is not the same as an investigation. Beyond that, state medical boards should review the policies and procedures for working with physicians who are impaired to provide safe care to patients and protect them.

Greater legal, legislative, and organizational advocacy led by physicians to protect physician rights, privacy, enforcing existing laws and creating a culture of trust and transparency between healthcare workers, patients, and boards/oversight organizations could also reduce the impact of judicialization on burnout [61].

Limitations

Suicide reports vary by country and location for various reasons. One reason is that suicide data is collected from multiple incomplete sources. Different locations and organizations may have challenges in reporting or identifying suicides. Further, they may lack the resources to gather information, or the data are not collected

systematically and reliably [61]. These data may be incorrectly codified, whether this is due to lack of information available (e.g., death of unclear intent), due to negligence, or due to intention (e.g., physicians not reporting the death of a colleague as suicide to spare the feelings of the family and for life insurance). Hence, medical schools and healthcare organizations often do not fully record student and physician suicide deaths [61]. Besides, doctors may be unwilling to classify a colleague's death as suicide but prefer an accident [16, 50]. As an example, Carpenter et al. (1997) showed that most accidental poisonings in physicians, which committed suicide, involved prescription drugs. Well, it seems implausible that consultants would be more likely than the general population to take a fatal overdose inadvertently [50]. However, this does not seem to have occurred for female consultants' deaths [50]. Broad study locations, period, and methods (e.g., different International Classification of Diseases codes and data sources) are also limitations. Nevertheless, Richings et al. (1986) have shown that a broader definition of suicide does not significantly change the overall picture of excess mortality from suicide among physicians [46]. Moreover, recent studies are focused on addressing quality scores, analyzing the heterogeneity of the samples, undercover publication bias, and implementing meta-regression to increase their validity [1].

Limitations proposed by Von Brauchitsch [68] for physician suicides studies are: (i) the examination of successful suicides rather than attempted suicides, (ii) small sample sizes, under which he includes studies of proportionate deaths, and (iii) insufficient standardization [65], with exception to (i) were ultimately trespassed by the meta-analysis aforementioned [1, 13, 14].

Conclusion

In conclusion, the great extension of intricate and contradictory findings indicates the need for more research in physicians' suicidality. Current studies focus on the epidemiology of completed suicides. However, to a better understanding, future research should expand to the other aspects involving suicidality. The suicide of physicians suicide can be mitigated only through a multimodal approach, optimizing the recognition of suicides and their risk factors, and then addressing systematic problems. The interaction of nonmodifiable risk factors such as sex, race/ethnicity, age, and educational attainment/healthcare career and location require further investigation [1, 13, 14].

Development · Perinatal risk factors · Cognitive development · Behavioral problems · Emotional problems · Peer victimization · Suicidal ideation · Suicide attempt · Suicide

Introduction

Suicide is a complex and multifactorial phenomenon [1]. Mental disorders such as depression and substance abuse are main factors contributing to suicide risk [2]. The stress-diathesis model of suicide posits that proximal environmental stressors, such as economic breakdowns and relationship problems, increase the risk of transitioning from suicidal ideation to suicide acts, especially among vulnerable individuals [3]. Beyond the documented influence of such proximal risk factors, a body of research suggests that distal factors occurring during development (perinatal, childhood, and adolescence) may also increase risk of suicide later in life. From a population-based perspective, identifying and understanding developmental factors associated with suicide risk is important to guide the development of new preventative interventions taking place early in life.

In this chapter, we aim to discuss the contribution of various factors taking place in key developmental periods that could contribute to suicide risk. First, we present evidence on the association between in utero and perinatal factors with suicide, suicide attempt, and suicidal ideation over the life span. Subsequently, we focus on factors related to three broad developmental areas: cognitive, behavioral and emotional, and social development. During the last decades, substantial research has been conducted to understand the influence of developmental factors on suicide risk from different perspectives: psychological, epidemiological, neuroscientific, and molecular. Here, we largely rely on epidemiological evidence, in particular from longitudinal studies following up children from the general population.

In Utero and Perinatal Influences

Numerous studies have provided evidence of the association between in utero and perinatal factors (including in utero conditions, maternal-related factors, and socio-economic environment at birth) and later health problems. These studies should be

interpreted in the wider context of the developmental origin of health and disease (DOHaD) model, which states that events occurring early in life can have long-lasting influence on health and diseases [4], including mental health [5]. A seminal work published 35 years ago opened the investigation of the perinatal influences on suicide risk. It investigated 46 risk factors from the prenatal, birth, and neonatal records of 52 adolescents who died by suicide and matched controls. Factors such as respiratory distress at birth, absence of antenatal care before 20 weeks of pregnancy, and chronic disease of the mother during pregnancy were found to distinguish adolescents who died by suicide from controls [6]. However, as early-life factors and suicide-related outcomes are rare in the general population, larger samples with sufficient statistical power are needed to reliably establish such associations. This field of research has moved further in recent years owing to the aging of participants enrolled in large birth cohorts and to the possibility of linking several population registers (e.g., in Northern-European countries). To illustrate, several studies have been able to identify early-life risk factors associated with increased suicide risk, such as low birth weight, teenage motherhood, and exposure to impoverished socioeconomic environment [7, 8]. Available evidence on the association between in utero and perinatal factors and suicide-related outcomes have been recently summarized in a systematic review and meta-analysis of all available longitudinal studies conducted in general population samples [9]. This study identified 42 articles including data from 21 cohorts from Europe ($n = 15$), North America ($n = 3$), Taiwan ($n = 1$), New Zealand ($n = 1$), and Brazil ($n = 1$), with sample sizes ranging from 140 to over 3 million participants, following participants for up to 89 years. The majority of the studies investigated suicide mortality as an outcome ($n = 14$) although some studies also investigated suicide attempt ($n = 9$) and suicidal ideation ($n = 4$). Although a wide range of perinatal factors were investigated in these studies, only for 14 of them were there enough evidence (≥ 2 studies) to perform a quantitative meta-analysis. This study reported several associations between family and parental characteristics and suicide-related outcome (Fig. 1).

Increased risk of suicide was found for individuals with high birth order. Specifically, compared to first-borns, individuals born second/third or fourth or more in the birth order were at higher risk of suicide mortality. There is convincing evidence from studies using within-family design that this association is robust to familial confounding factors (such as socioeconomic conditions and parental mental illnesses). For example, a Swedish study that investigated suicide risk in sibling groups of two or more children, in which at least one died by suicide, found that each increase in birth order was related to an 18% increase in suicide risk [10]. Other parental and family characteristics associated with increased risk of suicide and suicide attempt identified in the meta-analysis were teenage motherhood and family structure. In this line, several studies found that individuals born from a younger mother (aged 20 years or less at childbirth) were more likely to die by suicide compared with individuals born from older mothers, with a pooled meta-analytic odds ratio (OR) of 1.80 [9]. A similar risk was found for offspring born in nonintact families (e.g., single mother), compared to those born in intact families. Although the meta-analysis could not find evidence of increased suicide risk associated to

Fig. 1 Summary of the results of the meta-analyses of in utero and perinatal risk factors for suicide. (Note: The figure reports the pooled meta-analytic estimates (odds ratio) for the associations between different in utero and perinatal risk factors and suicide [9])

paternal age, one study using a robust within-sibling design reported increased risk of suicide attempt for offspring born to fathers aged 45 years or older compared with fathers aged 20–24 years [11].

Characteristics of the socioeconomic environment in which the child was born were strongly associated with suicide mortality, suicide attempt, and suicidal ideation across the studies included in the meta-analysis. For example, offspring of parents with low levels of education or low socioeconomic status (e.g., unskilled job) at the moment of childbirth were about 20–40% more likely to die by suicide and 70% more likely to attempt suicide in their life span [9]. The meta-analysis also reveals an association between indices of poor fetal growth and suicide risk. Individuals born with a low birth weight (<2500 g) were more likely to die by suicide, attempted suicide, and have suicidal thoughts compared to those with normal birth weight, even when taking into account children's gestational age [12]. Prematurity *per se* (i.e., a gestational age of ~37 weeks or less) was not associated with increased risk of suicide but was associated with increased risk of attempting suicide. Quasi-experimental evidence also pointed toward a possible causal role of birth weight in the pathway leading to suicide attempt [13].

Several studies investigated associations between obstetric characteristics and suicide-related outcomes, but no statistical evidence of association was found in the meta-analysis. For example, no increase suicide risk was reported for children born by caesarean section (versus vaginal delivery), for placenta abruption, and from low (i.e., <7) Apgar score. However, a small but significant association between cesarean section and suicide attempt was reported in one Swedish study [7]. Finally, associations between exposure to maternal physical (e.g., pregnancy hypertension) and psychological (e.g., stressful life events experienced by the mother while pregnant) factors during pregnancy were investigated for their associations with suicide risk, but no clear evidence of association was found [9]. For maternal smoking during pregnancy, associations were not consistent across studies, and the crude meta-analytic association only approached statistical significance (OR, 1.56; CI, 0.99–2.46). However, in single studies, no clear dose-response association was found between the number of cigarettes smoked per day and suicide risk. In addition, associations were strongly attenuated when the analysis was restricted to sibling pairs discordant for suicidal acts and prenatal smoking exposure [14]. These findings mine confidence on the existence of an association.

Taken together, findings from this meta-analysis suggested that some in utero and perinatal factors are associated with increased suicide risk across the life course, with main contribution of impoverished family and socioeconomic environment and restricted fetal growth. However, the meta-analysis also pointed out that evidence was scarce for some salient questions. Specifically, evidence for suicide attempt and suicidal ideation is still limited, as very few studies documented associations between perinatal factors and these outcomes. Additionally, mechanisms explaining associations between in utero and perinatal factors and suicide related-outcomes are still poorly understood. A recent study based on the Québec Longitudinal Study of Child Development (QLSCD) and the Avon Longitudinal Study of Parents and Children (ALSPAC), two birth cohorts respectively from Canada (province of Québec),

and the United Kingdom (county of Avon) addressed these gaps [15]. The study documented patterns of associations among 32 adverse perinatal factors (including fetal, obstetric, psychosocial, parental mental health and substance use problems), identifying 5 profiles of children characterized by exposure to certain categories of risk factors (Fig. 2): (1) *Poor fetal growth* (4.6–5.2%), including children not only with the highest probabilities of showing fetal growth adversity, but also with high probability of other adversity such as birth/delivery adversity, psychosocial adversity and to be exposed to maternal smoking in pregnancy, and with mothers experiencing depression; (2) *Psychosocial adversity* (16.5–21.6%), including children with the highest probabilities of psychosocial adversities, exposures to smoking, drugs, alcohol, and medications during pregnancy, parents with history of delinquent behaviors, and experiencing depressive symptoms; (3) *Delivery complications* (16.6–24.5%), including children born with caesarean section and having longer neonatal hospitalization; and (4) *Parental mental health problems* (7.8% in ALSPAC only), including children with parents experiencing high levels of anxiety and depressive symptoms; (5) the remaining children were part of the *No perinatal risk profile* (49.5–53.9%), including children with average probability of all perinatal adversity factors.

This study found that children in the *Poor fetal growth* and *Psychosocial adversity* profiles were at higher risk of attempting suicide by age 20 years, compared to children in the *No perinatal risk profile*. These findings were in line with the results

Fig. 2 Perinatal adversity profiles in the Avon Longitudinal Study of Parents and Children. (Note: The plots show the prevalence of the investigated perinatal adversity factors for each identified perinatal adversity profile [15]. Colors indicate categories of risk factors as described in the legend)

from the meta-analysis described above [9], suggesting that perinatal risk factors pertaining to poor fetal growth and adverse socioeconomic environment increase the risk of suicide attempt by late adolescence. Additionally, the study found evidence of increased risk of attempting suicide among children in the *Parental mental health problems* profile, compared to those in the *No perinatal risk* profile. To better understand why children with poor fetal growth and exposed to socioeconomic adversities or parental psychopathology were more likely to attempt suicide, the authors conducted a mediation analysis. The objective was to clarify to what extent externalized (e.g., conduct and impulsivity-inattention), internalized (e.g., anxiety and depression), interpersonal (e.g., exposure to peer victimization), and cognitive (e.g., poor verbal intelligence) problems during childhood (ages 6–12 years) accounted for the observed associations between psychosocial and poor fetal growth adversity profiles and suicide attempt. Two patterns of association were found: On the one hand, the increased risk of suicide attempt of children exposed to psychosocial adversities was largely explained by the investigated childhood problems (i.e., around 40% of the association was accounted for by these problems). Therefore, prevention of these problems across childhood may potentially help reducing suicide attempt in young people if associations are causal. On the other hand, internalized, externalizing, interpersonal, and cognitive problems only explained a small proportion of the increased suicide attempt risk of children exposed to fetal growth adversities and parental mental health problems. Therefore, prevention of these problems for those children would have a limited effect on reducing their suicide risk, and it is critical to identify other mechanisms implicated in this pathway.

Cognitive Development

Cognitive development refers to the acquisition of skills such as information processing, conceptual reasoning, language learning, and problem solving which help individuals to think about and understand the world around them. Cognition is a key determinant of both physical and mental health [16]. Numerous studies have reported differences between individuals who attempted suicide and controls on several neuropsychological markers, such as executive functions, memory, and decision-making [17, 18]. While these studies highlighted the role of cognition in the vulnerability to suicide, their contribution to the understanding of cognition-to-suicide link from a developmental perspective is limited, as they mostly relied on cross-sectional samples of clinical adults. Recently, large longitudinal studies (specifically those using administrative data from Scandinavian countries) were able to investigate associations between cognition during childhood and adolescence (measured using either intelligence tests or school performance assessments) and suicide-related outcomes in the general population. Overall, these studies showed an inverse association between cognitive skills in childhood and adolescence (ages 7–18) and later suicide risk [19–22]. For example, a Swedish study based on more than 20,000 individuals with information on intellectual quotient (IQ) in early adolescence reported that lower IQ scores were associated with increased risk of suicide in

midadulthood in women [23]. Other studies measuring IQ in young adult men at conscription showed an inverse association between IQ and risk of suicide attempt and mortality 30 years later [24, 25]. In another large Norwegian cohort including 610,359 participants, poorer academic performance at age 18 years predicted increased risk of suicide mortality up to three decades later [26]. These results were similar to those reported in a Swedish study showing that risk of hospitalization for self-inflicted injury increased steeply with decreasing grade point average from the last year of compulsory school [27]. A recent study also provided evidence of long-term stability of the association between IQ at ages 18–20 years and suicide attempt and mortality up until age 59 years [28]. Worth noting is also the linearity of the association between IQ and suicide, with a constant increase of suicide risk for each unit of decrease in intelligence across the whole distribution (Fig. 3).

Most of the previously cited studies established associations between adult suicide-related outcomes and cognitive and academic skills assessed at one single time point (usually in adolescence or early adulthood). However, a single assessment of cognitive skills cannot inform on whether cognitive differences were always present, or they emerge during development. To fill this gap, a recent study based on the 1958 British Birth Cohort [22] assessed academic skills at multiple time points in childhood (7 and 11 years) and adolescence (16 years). This study estimated trajectories of academic performance in both mathematics and English reading in individuals who later died by suicide and those still alive. The results, depicted in Fig. 4, showed that while males who died by suicide did not differ from participants still alive in reading scores at age 7, their reading scores had a less steep improvement up to age 16 compared to other participants still alive (a similar pattern

Fig. 3 Association between IQ and suicide risk in 1,109,453 conscripted men (17,736 suicides). (Note: IQ category 9 (lowest performance) is the reference category. Fig. 4 Trajectories of reading and mathematics skills during childhood and adolescence for individuals who died by suicide by age 50, and individuals still alive in the 1958 British Birth Cohort. (Note: Dotted lines represent the observed values, while solid lines represent the values estimated using a growth model [22])

was observed for mathematics scores). This suggests that differences in academic skills between suicidal and nonsuicidal individuals are likely to emerge in the course of childhood and adolescence, rather than being detectable since early childhood.

While mediators that might explain associations between cognitive/academic skills and later suicide are rarely studied, several factors might contribute to these associations. First, poor capacities to solve problems have been hypothesized to play a role [29]. Indeed, people with lower cognitive skills may have poorly developed problem-solving abilities, which in turn may be a barrier to identify solutions during a crisis situation. This hypothesis is supported by evidence showing associations between problem-solving deficits and suicide attempt and the efficacy of problem-solving therapies in preventing suicide reattempt [30]. Additionally, in the abovementioned study of Swedish conscripts, it was shown that the logical (problem-solving) subscale of an IQ test exhibited the strongest association with suicide compared to the other subscales [24]. Second, the association between cognition and suicide-related outcomes might be explained by unhealthy behaviors such as smoking and low physical activity [31], which are associated with both poor cognition and suicidal risk. Third, poor cognitive skills and interruption of schooling may limit job opportunities, which may impact on adult socioeconomic position and job security, which in turn may increase suicide risk [20]. It is also worth noting that confounding factors may also explain the associations between poor cognitive skills and suicide risk. Poor cognitive skills in early childhood and adolescence are associated with less favorable socioeconomic conditions across the life span (such as availability of resources, quality of the educational environments, parental educational level, place of residence, financial stress, and single parenthood). All these factors can confound the association between cognitive skills and suicide, as they are determinants of poor mental health and suicide risk as well as cognitive skills [21, 22, 32]. The extent to which these variables explain the association between cognitive skills and suicide varies across studies. In large studies, associations are usually modestly attenuated when these confounders are taken into account [24, 25]; however, in studies with less statistical power, associations appear to be fully accounted for by these confounding factors [22].

Behavioral and Emotional Development

With the overarching aim of identifying children at higher suicidal risk later in life, several researchers investigated associations between behavioral (i.e., externalizing symptoms such as impulsive, aggressive, and conduct problem symptoms) and emotional (i.e., internalizing symptoms such as anxiety and depressive symptoms) problems and suicide-related outcomes [8, 9, 33–38]. Overall, both childhood behavioral and emotional problems have been associated with higher suicide risk in those studies. However, associations may vary according to the specific suicide-related outcomes and age. For example, while childhood and adolescent emotional problems are associated with both suicidal ideation and suicide attempt, behavioral problems and the co-occurrence (comorbidity) of both behavioral and emotional

problems seem to be only associated with suicide attempt and mortality [34, 39–41]. Additionally, studies have shown that although emotional problems make strong contributions to suicide risk throughout the life course, behavior problems are more salient predictors of suicide risk in adolescents and young adults, whereas emotional problems have a more important role at older ages [1].

Childhood impulsive-aggression and related behavioral traits, such as irritability [42], were also investigated for their associations with suicide-related outcomes [43–47]. Distinguishing among these different constructs is challenging due to their partial overlap, differences in definition, and diversity of assessment measures [48]. Of note, these constructs all describe dysregulation in mood and tendency to aggressively overreact to external stressors.

There is evidence suggesting that impulsive-aggressive traits are part of a developmental cascade that increases suicide risk, especially in younger individuals [49]. To illustrate, based on a large cohort of individuals who died by suicide, McGirr et al. showed that levels of impulsive-aggression were inversely associated with the age at which individuals died by suicide [49]. Furthermore, the contribution of impulsive-aggression to suicide risk was relatively independent from comorbid psychopathology (such as depression). Impulsive-aggression is conceptualized as being a distal and predisposing risk factor contributing to the diathesis for suicide risk (Fig. 5) [44]. In line with this conceptualization, a twin study showed that a large proportion (~50%) of genetic factors contributing to individual differences in childhood impulsive-aggression (6–12 years) also contributed to individual differences in suicide risk by age 20 years, suggesting the existence of common genetic influences underlying both impulsive-aggression and suicide risk [45].

From a developmental perspective, a series of studies conducted in the QLSCD investigated the association between repeated measures of irritability in childhood and suicidal ideation and attempt in adolescence and early adulthood [35, 36, 40, 50]. Irritability is a concept that encompasses both behavioral and emotional problems, as it includes both mood changes (becoming irritable, cranky) and behavioral manifestations (aggression against oneself, others, or objects) [51]. In the QLSCD, both aspects of irritability have been captured using four items rated by elementary school teachers at child age 6, 7, 8, 10, and 12 years: “has temper tantrums” (for the mood component) and “reacts in an aggressive manner when teased/contradicted/something is taken away from him or her” (for the behavioral component). Four developmental trajectories of irritability described the heterogeneity in the course of irritability symptoms during childhood (Fig. 6): Most children had low levels of irritability throughout childhood (75%, low trajectory); some had high levels of irritability that persisted over time (5%, persistent trajectory); others had very high symptoms of irritability in kindergarten, but that decreased during childhood to disappear at age 12 years (7%, declining trajectory); and finally, others presented few symptoms of irritability at the end of kindergarten, but which increased during childhood until adolescence (13%, rising trajectory).

Children on a persistent irritability trajectory and those on a rising irritability trajectory were more likely to report suicidal thoughts or suicide attempt in adolescence, compared to children who did not show symptoms of irritability during

Fig. 5 Model of the hypothesized relations among risk factors for suicide. (Note: The figure reports a model of the hypothesized relations among different variables contributing to suicide risk [49])

Fig. 6 Trajectories of childhood irritability in the Québec Longitudinal Study of Child Development. (Note: The figure shows the trajectories of irritability from ages 6 to 12 years of 1393 children enrolled in the Québec Longitudinal Study of Child Development [35]. Dots represent observed values, and solid lines represent trajectories as estimated by our model. (Data were compiled from the final master file of the Québec Longitudinal Study of Child Development (1998–2018), ©Gouvernement du Québec, Institut de la statistique du Québec))

childhood. Children who had high irritability symptoms in kindergarten but not afterward (declining trajectory) were not at increased suicide risk compared to nonirritable children. Interestingly, Orri et al. showed that the highest suicide risk was found for children who presented with both high irritability symptoms and high anxio-depressive symptoms in childhood: For these children, the rate of suicidal ideation and suicide attempt was twice as high as for children with only high anxio-depressive symptoms without irritability [36]. This finding, which is in line with a previous study in another Canadian cohort [52], might carry important implications for identification of children at risk for suicide. Indeed, irritability is a symptom present in many, but not all, children with depression/anxiety. Therefore, these results suggest that among children with anxio-depressive symptoms, the presence of irritability would facilitate the identification of those with a greater suicide risk.

Studies on the QLSCD also contributed to the understanding of the mechanisms explaining the association between childhood irritability and suicide risk. A better knowledge of the underlying mechanisms might be a first step to guide the development of preventive strategies for irritable children. A first study aimed to clarify whether irritability during childhood is directly associated with a higher suicide risk, or whether it is an early marker of mental health problems (depression, anxiety,

hyperactivity, and aggression/opposition) contributing to suicide risk [35]. Results indicated that for children with persistent irritability, mental health problems (especially depression) explained a substantial proportion of the suicide risk, suggesting that irritability could be an early marker of depression for these children. However, for children with rising levels of irritability during childhood, mental health problems explained only a small part of the suicide risk, suggesting that for these children irritability itself (or other unmeasured mechanisms) increases the risk of suicide. A second study investigated environmental mediators of the association between childhood irritability and adolescent suicide attempt [40], specifically focusing on two putative mediators: peer victimization and harsh parenting in early adolescence (age 13 years), both previously associated with suicide attempt [53–56]. Indeed, prior evidence suggested that irritable children are more likely to be exposed to negative interpersonal experiences, including peer victimization and harsh parenting [57–59]. Other studies also reported associations between childhood irritability and parenting styles characterized by harshness and hostility [60, 61]. Therefore, victimization and harsh parenting were plausible mediators of the association between irritability and suicide risk. In their study, Forte et al. showed that a substantial portion of the risk of attempting suicide for children following persistent and increasing irritability trajectories was explained by the increased exposure to peer victimization [40]. This finding is in line with the failure model [62], which states that children showing aggressive behaviors, such as being irritable, exhibited poorer social skills, greater rejection by peer, and less social support, which in turn put them at risk for negative outcomes such as suicidal ideation and suicide attempt. However, no evidence was found for a mediation role of harsh parenting in the association between irritability and suicide risk [40]. This finding may indicate that parenting in early adolescence plays a marginal role on suicide risk or irritable children; however, it is not possible to exclude that parenting at an early age may play a more central role, and future studies are needed to better clarify this issue.

Social and Interpersonal Development

Social development refers to the process by which children learn to interact with others around them including cooperating and communicating with others, establishing friendships and handling conflict with peers. Social development is suspected to have a profound impact on other developmental domains and on children's life experiences, including the quality of peer relationships especially within the school context. In this chapter, we focus on one aspect of social development that has received considerable attention in relation to suicide risk: peer victimization. Peer victimization is the experience among children of being the target of the aggressive behavior of other children [63]. It can include being pushed or hit, being called names, group exclusion, and cyber bullying. Bullying is a specific form of peer victimization, which is characterized by an imbalance of power between the perpetrator and the victim, as well as repetition of the acts [64]. While children from diverse cultural and geographic backgrounds are exposed to

bullying-victimization [65], it is more prevalent in children that are different from the social norms, including disabled children [66], obese children [67], and sexual minority youth [68]. Most children experience some form of bullying-victimization during childhood, and the frequency decreases with age [69, 70]. However, the experience of being bullied-victimized is highly heterogenous, varying in severity and chronicity. About 10–15% of children experience persistently high levels of peer victimization from elementary to high school [69, 70]. An important modifiable factor for children to be chronically victimized by their peers across their education is high levels of disruptive behavior before school entry [70].

It is important to understand the role of bullying-victimization in suicidal risk for several reasons. First, in the news, a number of high-profile suicides have been attributed to bullying-victimization. Second, interpersonal conflicts and relationship difficulties are often cited as key precipitant of suicide deaths in psychological autopsy studies [71], and bullying was reported in about one quarter of suicides in people younger than 20 years [72]. Third, bullying-victimization is associated with increased risk of mental disorders including depression, substance abuse, and psychotic symptoms [73] which in turn are associated with suicide [1]. Fourth, bullying-victimization is common, and reducing rates of bullying-victimization could potentially help reducing suicidal risk at the population level, if the association is causal.

Several studies have examined concurrent associations of bullying-victimization and suicide ideation and attempt. In a large survey of 134,229 adolescents around the world, bullying-victimization was associated with three times the odds of attempting suicide in 47 of the 48 countries studied [74]. A significant proportion of youth who are the victims of their peers are simultaneously bullying others. Previous research [75] including a meta-analysis of 47 cross-sectional studies found stronger associations for adolescents with the bully-victim status, as compared with those who only bully or are only victims [76]. Concerns have been raised that cybervictimization which is expressed through electronic forms of communication such as social media or texts has the potential to cause more distress than traditional bullying-victimization. Cybervictimization often co-occurred with traditional bullying-victimization, and most of the time the perpetrators were students of the same school [77]. In the QLSCD cohort, it was found that about 7–16% of adolescents between the ages of 12 and 17 years reported being cybervictimized in the past year, and for the vast majority of them it has happened only once [77]. In line with two meta-analyses [78, 79], the later study also suggested that cybervictimization (alone or when combined with face-to-face victimization) was more strongly related to suicidal ideation than traditional bullying-victimization in the short term (Fig. 7).

One concern that emerged from these cross-sectional studies is that they were unable to confirm the direction of the association. This is important because factors that are associated with increased risk of being bullied-victimized by others, such as depressive and disruptive symptoms, are also associated with suicide risk [80]. Hence, from cross-sectional studies alone it is still unclear if bullying-victimization is a risk factor for suicidal ideation and suicide attempt or whether associations merely reflect the effect of unmeasured confounders.

Fig. 7 Association of traditional bullying-victimization, cybervictimization, and their combination with suicidal ideation/attempt. (Note. The figure reports the odds ratios for the association between different combinations of exposure to traditional bullying-victimization and cybervictimization and suicidal ideation and/or attempt in the Québec Longitudinal Study of Child Development [77]. (Data were compiled from the final master file of the Québec Longitudinal Study of Child Development (1998–2018), ©Gouvernement du Québec, Institut de la statistique du Québec))

For obvious reasons, individuals cannot be randomly assigned to bullying-victimization groups, therefore limiting strong inferences on the effects of bullying-victimization on suicide risk. Thus, in the absence of randomized experiments, longitudinal studies with assessments of child and family characteristics, prior to bullying-victimization, are the stronger designs to assess such associations and strengthen causal inference. In one study, Geoffroy et al. (2016) found that adolescents exposed to bullying-victimization were two times more at risk of thinking about suicide and three times more likely to attempt suicide 2 years later, after accounting for baseline suicidal ideation/attempt, mental health symptoms, and family hardship [53]. In another study, the team reported an association between chronic peer victimization and later suicidal ideation that was not only independent from prior mental health symptoms, but also from concurrent depression and anxiety problems [69]. Other research suggests that the effect of bullying on suicidal ideation can last well into the adult life (for review: [81]). For example, in the 1958 British Birth Cohort, individuals who were frequently bullied in childhood were found to be at increased risk of suicidal thoughts 40 years later [82], after taking into account internalizing and externalizing symptoms in childhood and adverse experiences. To

date, a focus of research has been on suicidal ideation or on suicide attempt, with, to our knowledge, only one prospective study investigating the association between bullying and suicide mortality. In the Finish 1981 Birth Cohort Study, being the victim of bullying in childhood was associated with later suicide attempt and suicide mortality, after controlling for prior conduct problems and depression symptoms [83]. The magnitude of association was much stronger in females than males. To date, studies on the long-term effect of cybervictimization on suicidal ideation and suicide attempt are lacking. One study examining the effects of cybervictimization on suicidal ideation 2 years later, accounting for baseline suicidal ideation and related mental health symptoms, did not find cybervictimization to be associated with suicidal ideation in the long term, while face-to-face victimization was associated with suicidal ideation in the long term [77]. One possible explanation is that cybervictimization often occurs in isolation while face-to-face victimization is more chronic [69] and potentially contributes to a stronger prospective association.

Importantly, longitudinal studies with statistical adjustment cannot account for confounding factors that were not measured, including genetic vulnerabilities. One recent study based on the ALSPAC cohort found that children who were bullied-victimized by others were more likely to carry a range of genetic vulnerabilities that in turn are associated with increased risk of mental disorders and suicide [84]. Using the Environmental Risk Longitudinal Twin Study, Baldwin and colleagues (2019) used a cotwin control design to examine whether adolescents with the same genotype, individual and family vulnerabilities, but not the same exposure to bullying-victimization had different suicidal risk. Although prior vulnerabilities account for a large proportion of the bullying-victimization/suicidal risk association, victimized adolescents still showed a risk of suicidal ideation compared to nonvictimized adolescents, pointing to a causal association (Fig. 8) [85].

Taken together, these studies suggest that bullying-victimization is a risk factor for suicidal ideation and suicide attempt, but evidence for suicide mortality is lacking. Future studies are needed to test whether reducing the occurrence of bullying translates into a reduction in suicidal ideation and suicide attempt. Other strategies that do not aim directly at reducing bullying can also be beneficial. For instance, a simple intervention such as encouraging families to eat dinner together has been found to help adolescents exposed to cyberbullying to cope with their suicidal ideation [86]. In addition, a large-scale study found that bullied adolescents who exercise frequently were less likely to think about suicide than those who did not exercise [87].

Conclusion

This chapter summarized evidence on the influence of developmental factors on later suicide risk, including on suicidal ideation, suicide attempt, and suicide mortality. Overall, epidemiological evidence presented here suggests that suicide risk in adolescence and throughout adulthood has roots in the developmental period. Studies focusing on the prenatal and perinatal period suggested that early-life

Fig. 8 Association between peer victimization and suicidal ideation, suicide attempt, and self-harm using different approaches to account for confounding factors. (Note: The figure shows the odds ratio for the association between adolescent peer victimization and suicide-related outcomes in the Environmental Risk Longitudinal Twin Study. characteristics are associated with increased suicide risk throughout the life span, with main influences represented by unfavorable family or socioeconomic characteristics, restricted fetal growth, and exposure to parental mental health problems. Later, in childhood and adolescence, cognitive and socioemotional factors appear to play important roles in the pathway leading to suicide. On the one hand, poorly developed cognitive skills in childhood and adolescent may have a long-lasting impact on socioeconomic status (including job security and position), which may result in exposure to more adversities in adulthood and lack of problem-solving abilities, in turn increasing suicide risk. On the other hand, behavioral and emotional problems during childhood are an important marker of vulnerability to suicide. In particular, emotional dysregulation (e.g., difficulties to regulate mood and behavioral responses when facing life stressors) and comorbidity of emotional and behavioral problems seem to play a key role in the etiology of suicide risk. Finally, interpersonal problems with peers during the school period, especially being the target of peer

victimization, can have impacts that go beyond the school period to influence later suicidal risk.

In reading the evidence we presented here, it is important to acknowledge three aspects. First, all the dimensions of development we discussed are not independent from one another. For example, poor fetal growth may influence later cognitive and behavioral development through alterations of neurodevelopment [88]. Low cognitive skills may influence how children regulate their behaviors and emotions, understand social cues during interactions, and interact with peers [89, 90]. Children with behavioral problems such as irritability may elicit negative reactions from the environment such as being excluded from the social circles or being victimized [57]. Victimized children tend to develop depressive cognitions [91]. It is therefore essential to adopt a multidimensional perspective that considers all these different aspects of child development as interdependent and mutually influencing each other.

Second, to translate these findings into public health-preventive strategies, more research is needed, particularly from long-term experimental programs in population sample [92]. However, the findings we presented suggest that routine psychosocial assessment of new mothers (e.g., by obstetricians and social workers) and of child development (e.g., by pediatricians) should be introduced to identify potential psychosocial, socioeconomic, and environmental factors that may signal higher risk for later offspring mental health problems. Such assessment may identify at-risk families and children that may benefit from interventions. For example, home-based interventions and interventions focusing on parent-child interactions show to have short- and medium-term positive effects of child mental health and cognitive development [93, 94], which can buffer later suicide risk. Evidence is also available for long-term effects of such early interventions [95]. For example, a counseling-based intervention relying on both home visits and parent groups for low birth weight and preterm children showed to be effective in improving children's cognitive development and reducing criminal behavior and socioeconomic hardship in young adulthood. The level of evidence of such intervention on the reduction of suicide risk is still low, and future long-term intervention studies should consider assessing suicidal thoughts and behavior as outcomes, alongside with other more commonly studies outcomes. It is also worth noting that all such distal interventions are a-specific in nature, as their aim is to improve different aspects of child development from the early years of life. These developmental aspects are likely to mediate any potential positive effects on suicide risk. Therefore, rigorous studies documenting the association between child developmental and suicide-related outcomes are important in order to support the hypothesis that improving in specific development areas (e.g., cognitive, behavioral, and social) can lead to a reduction of suicide risk.

Third, this chapter is not intended to be a comprehensive presentation of all developmental influences on suicide. Rather, we focused our attention on some important aspects, but we did not focus it on other equally important ones. Three aspects, in particular, have not been tackled. The first one is maltreatment (e.g., child neglect and abuse), an adverse experience often occurring in childhood which has profound impact on subsequent biopsychosocial development and suicide risk [96].

The second is alcohol and substance abuse, which have their onset in adolescence, are linked with both cognitive and behavioral modification (e.g., impulsivity), and are strong predictor of suicide [97]. The third one is physical development, and specifically puberty, which has been linked to suicide risk in previous rigorous longitudinal studies [98].

In conclusion, the findings presented in this chapter stress the importance of the developmental periods from birth to adolescence as windows for suicide prevention at the population level. Although more research is needed to translate these findings into preventive interventions, it is important to consider such factors in the current models of suicide.

Abstract

There is an urgent need to understand the effects of social media and related practices in the aftermath of a suicide. News of a death by suicide can explode like a bomb on social media, the impact of which can be felt around the world. Emerging research has shown that activity very often prompts multiple users to respond, rapidly sharing posts and ruminating publicly about the nature and reasons for the death. Knowledge about the role of online communication in the aftermath of a suicide is extremely limited, as is the impact of exposure in this way. Very little is known about the experiences and needs of those who engage in social media practices in the aftermath of a suicide: who engages in these practices; when do they emerge; how do they evolve over time; what is the impact on the immediate and wider community of users; and implications for prevention and postvention.

579

In this chapter we draw upon existing and emerging literature to highlight how social media practices following a suicide loss increase exposure to suicide and have the potential to increase the risk of contagion. We reflect upon (a) the need for guidelines on safe reporting to be updated to account for the globalization of new media technologies, (b) the implications for postvention, and (c) the need for a new model for understanding the transmission of suicidal behavior via media exposure.

Keywords

Suicide · Social media · Exposure · Contagion · Prevention · Postvention

Background

In 2018, 6,507 suicides were registered in the UK [1]. It has been estimated that between 6 and 60 people in the extended social networks of those who die by suicide (friends, family, and acquaintances) are profoundly affected by each of these deaths [2, 3] and at significant risk for suicide [4, 5]. It is therefore possible to estimate between 39,042 and 390,420 people are affected each year and potentially made vulnerable to suicide. More recently, however, Cerel et al. [6] argued that the number of people exposed to each suicide death is far greater than this and more likely to be around 135 in US context at least.

We know that many of those exposed to suicide in various ways can feel stigmatized and traumatized and suffer from suicidal ideation [5, 7–9]. Research has also shown that at a time of high risk many of those who are affected use social media to express their sense of loss [10, 11]. How suicide is reported by the media and how it is talked about on social media impact suicide contagion (copycat suicide) [12, 13]. Young people in particular are susceptible to this by the words, images, and prominence of suicide stories.

Given that exposure to suicide can take many different forms, even Schiedman's [14] estimation of 6 growing to 60 [2, 3] and 135 [6] may be drastically underestimated in 2020. When taking into account exposure via social media, we propose that it is exponentially higher and far more difficult to quantify. Local news stories of suicide can now reach a global audience within days through sharing. A recent example in the UK highlights this: In December 2016 a 20-year-old man spoke of his heartache after breaking up with his girlfriend in an emotional post on his Facebook page and shortly afterwards took his own life. He ended the post by begging Facebook to not remove his post. In the days that followed, it was reported that the post went "viral": over 20,000 people viewed the letter (and Facebook page), which was shared around 11,500 times [15]. Another report suggested that over 50,000 people from different parts of the world responded to the post [16], including some negative comments prompting bereaved family members to speak out.

Sumner et al. [17] also argued that the population effects of exposure to suicide-related media are underestimated. They suggest that the range of impact from suicide

is expanding with increased connection possible through online social networking services such as Facebook. Individuals today are empowered content creators and consumers at once [17]. With this increased connectivity and self-perpetuating spread of viral news, the range of impact from a suicide expands in multiple ways, promulgating detailed and intimate information and sensationalizing how the death is seen. Local news can reach across the globe in moments; users of new media can affect people they will never know with a single comment.

At the time of writing, the userbase of Facebook alone is currently 2.7bn with an average of 338 “Friends” per person and only 3.57 degrees of separation between everyone; three quarters of Facebook users visit the site daily, and 50% visit it multiple times per day [18]. Many posts and shares reach friends of friends, again multiplying the exposure rate at a rate that is virtually instantaneous (as in the example given above). It is not difficult to imagine how rapidly the number of people exposed to suicide in this way and thus made vulnerable multiplies. This global network and algorithmic exposure to suicide via social media is difficult to quantify. No enquiry into how the information is transmitted, or the implication for suicide postvention, currently exists.

Postvention refers to support, procedures, and interventions that take place after a suicide to alleviate the distress of bereaved individuals (survivors), reduce the risk of imitative behavior (copycat suicides), and promote the recovery of the affected community. The term was first coined by Edwin Shneidman [14, 19] who noted that efforts at suicide postvention were a direct form of prevention of future suicides. In the UK, suicide postvention and care of the suicide bereaved is a NHS and public health priority: A key objective of the Suicide Prevention Strategy [4] is to “provide better information and support to those bereaved or affected by suicide.”

Cerel et al. [20] and Neimeyer et al. [21] acknowledged that understanding the impact of a suicide on social systems and individuals is now a major task for postvention research. They too recognized that those “exposed” are hardest to identify and constitute the group we know the least about. Likewise, little is known about the experiences and needs of those who engage in social media practices when someone in their social network – be it close or extended (friend of a friend) – dies by suicide.

Social media is at once open and private: it allows users to observe details of each other’s lives, but at the same time we each experience social media differently depending on our network of friends/follows (and interests, etc. which influence what appears on our feed). Much more needs to be known about the impact of exposure to suicidality on individuals in these networks, including how this medium works; why people use it; who engages in these practices in the immediate and wider community of users; when and where they emerge; and the contagion effects of social media practices.

Our research over the last 6 years has shed some light on this phenomenon. We have explored how social media use impacts surviving friends and family members in the aftermath of a suicide. We began by studying how deaths by suicide had been memorialized online, by conducting in-depth interviews with bereaved family members and friends who were using various online mediums to pay tribute – and in

many cases stay “connected” – to their lost loved ones. Our findings revealed both positive and negative effects of such practices. On the positive side, it was a means for the bereaved to transform their experiences and open up new ways of grieving and managing trauma. Participants described how they used sites (Facebook being the most common) to reach out to users in comparable circumstances of incredible shock, trauma, and sadness. Grievors had the resources to provide much-needed support for one another that lasted through the immediate aftermath of the suicide, continuing for many months, sometimes years after [8]. The sites provided an avenue of communication with deceased loved ones, highlighting clear implications for continuing bonds (staying emotionally and socially connected to the dead) and what many commentators refer to as the “continuing social presence of the dead” [10]. Negative effects included the potential for alternative narratives, increased distress, conflict, and suicide contagion [22].

In our most recent research [23], we interviewed individuals who had lost a loved one to suicide (i.e., bereaved parents, siblings, and friends) and practitioners working in various professional capacities to support those who are affected in the aftermath of a suicide. We sought to examine their experiences of media exposure (including social media and how this is used) and their perceptions of the impact of this on others in the community. In the following sections, we outline new insights from a preliminary analysis of this data which highlights how social media practices after a suicide loss increase exposure to suicide and the number of those affected. We discuss five themes in relation to existing research in the area and reflect on the impact for the immediate and wider community of users, implications for prevention and postvention, and how to target those in need of support.

Finding Out

Data from our recent interviews indicated that it is common for people to find out about a suicide via social media within hours of the event; this is consistent with findings reported by Heffel et al. [24] and Robertson et al. [25], who proposed that this was a factor suggestive of suicide contagion. For most people we spoke to, there was a race against the clock to tell everyone the “right way” in order to avoid negative impact. In the immediate aftermath of a suicide, the closely bereaved were often tasked with letting others who were close to the deceased know about the death. Once the media and social media find out, the news explodes; it is shared and commented upon, and personal messages are sent to the closely bereaved without consideration that this may be the first the viewer/recipient has heard of the death. This can be a jarring, impersonal, or even insensitive way to be exposed to suicidality and the death of someone one is potentially close to.

Heffel et al. [24] reported that one participant in their study learned about the suicide of their sibling via social media and expressed anger and regret. A participant in our study reflected on how lucky she was that her smartphone was out of battery on the day she would later find out about her brother’s suicide. Multiple messages were being sent to Louise’s phone, which would have caused her to find out about her brother’s death before her parent had the opportunity to tell her. Later, turning her

smartphone back on, Louise found that social media users had been eager to message her without considering that she might not actually know yet.

In the extract below, Louise's parent describes the speed with which the news was spreading and the panic she felt at the thought of her daughter finding out about her brother's suicide this way:

Oh my God. . . I can't cope with this. . . what if it comes out? What if the people at. . . [work] put it on Facebook or something like that? She could find out on the phone. . . all this time I'm trying to keep it off Facebook. I'd messaged. . . [other] people and. . . the Police, can you make sure that this doesn't. . . get out on Facebook because I'm worried about my daughter finding out?... within three hours, it was already buzzing round Messenger. (Cheryl)

Widespread Rumor and Speculation

It became evident that much of the information exchanged in this way was inaccurate. Widespread rumor and speculation served to fuel the exchange of messages and social media activity, further increasing awareness of the death and heightening the sense of anxiety and distress throughout the community, a finding also consistent with Robertson et al. [25]. Robertson et al. [25] argue that these electronic communications were likely to increase the risk of suicide contagion among young people through rapid sharing of information about the death facilitated by these technologies. Our interviews highlighted how, within hours of the death, activity on social media gave rise to rumor, and emotional outpourings which were shared online, as shown in this interview extract from a practitioner who worked in a postvention service supporting those affected by suicide:

The post went out and people started to panic and it got shared. . . thousands and thousands of times. . . the police got involved and they also shared it. . . It was very, very traumatic for everybody because it was so publicised. . . It got posted on social media, straightaway before any official announcement. . . [One] post had thousands and thousands of comments and different opinions on what had happened. . . different rumours and different stories. . . There was about six different versions of events of what happened. . . It was pretty chaotic to be quite honest. . . (Alison)

Mass Exposure

The example above illustrates how an exponential increase in exposure, which hits users repetitively, comes about via social media communication. Niederkrotenthaler et al. [26, 27] discuss this repetitious exposure in relation to media coverage of celebrity suicides, arguing that it increases the risk of suicidal tendencies among those who are vulnerable. Research by Scourfield et al. [28] compared social media communication in the aftermath of suicide deaths with that of road traffic accident deaths and found suicide memorial sites on Facebook generated thousands of postings. The same authors also found that suicide deaths attract more intensive attention and speculation and more elaborate writing and searching for meaning or

explanation for the death. Our data were consistent with this. The illustrative extract below from one of our interviews demonstrates how the circumstances of a suicide death garner media attention:

[Brother's death] was in the newspaper, there was like sharing articles, so the whole sharing side of it. . . was difficult because it was like my newsfeed all of a sudden became flooded with. . . my brother, my grief, my trauma. . . people. . . sharing and sharing and sharing. (Louise)

Until now, this phenomenon has only been seen when a celebrity takes their own life, and it is reported by the media, which ignites conversation among the public; now, the tendency for news of a suicide death to spread through social media allows this to happen to anyone. This celebritization adds fuel to the melee of online activity surrounding the death, which has the potential to increase contagion. Louise describes a dramatic change in the activity she witnessed on her social media following the suicide of her brother:

My newsfeed felt like a very dangerous place. . . it was hard. . . it felt a lot like swallowing poison (Louise).

She reflects that this danger was due to the death being made public through the mass exposure social media facilitates:

The fact that it was so public made it ten times worse. . . everyone was talking about it, it was just everywhere. . . Suicide is not like other deaths. . . the fact that it's suicide it's already ten times more amplified. . . because of the psychological chaos it causes. So for the public to add to that and have something to say. . . it just amplifies the chaos even more. (Louise)

Our data shows how exposure by social media reaches from those closely related to the deceased to those who are complete strangers:

One thousand one hundred and eighteen people like the page and one thousand one hundred and twenty-five people follow it. (Elizabeth)

Alison was not closely related to the deceased. Her comment here demonstrates how those in the wider community can be impacted by the suicide of a stranger:

I didn't know him, I didn't know the family, I didn't know anything about it but for the past three days I've been seeing everyone on Facebook sharing . . . it hits you in a way you can't quite explain. . . it's traumatic and it's kind of devastating to see. . . everybody in kind of the community we lived in, saw what had happened, so it did affect that wider community as well. (Alison)

When people are flooded with information about a particular suicide, vulnerable recipients can experience an increase in suicidal tendencies. It is no longer only in the reporting of a celebrity suicide that this reach occurs. The wildfire spread of such news via social media allows this phenomenon to occur with any other suicides, and more regularly.

Romanticization

Portrayal of a suicide in a way that glamorizes the tragedy or romanticizes those who have died by suicide can increase the risk of suicide contagion. Research by DeGroot [29], which looked at the ways in which deaths were memorialized online, noted the tendency for loved ones to use Facebook as a place to describe the deceased in a positive, almost romanticized way. We observed similar patterns in our data but also that this romanticization could be a factor in influencing suicide contagion, and this is what Robertson et al. [25] reported: many of those who took their own lives received attention and dedications from hundreds of other young people online which may have contributed further to the risk of contagion. Also consistent with Robertson et al. [25], a number of our participants expressed some concern over the idealization of the deceased among posts on social media, which could inadvertently contribute to the glorification of the suicide:

Making him out to sound like some sort of supernova. . . almost like godlike. (Louise)

Everybody that. . . wrote on it. . . saying what an amazing guy he was and... a fantastic man. . . making [him] into some sort of. . . like saintly figure. . . what an amazing person he was, . . . wonderful things. . . it built up his status almost. . . I think that could be dangerous for somebody who was mentally not in a good place. (Bridget)

As Bridget alludes above, the glorification of the deceased can pose a threat to vulnerable observers. The following extract demonstrates how this glorification can lead to the act of suicide itself being sensationalized and legitimized as a means of alleviating mental distress:

Suicide deaths almost becomes quite dramatic. . . it's a level of detail that sometimes gets sensationalised. . . normalisation and Facebook can. . . feed into that because these people who kill themselves are almost. . . glorified or thought very highly of and it's all that kind of acceptance that might well then lead into that contagion. . . it's like shining a light on suicide as a method of death and on the fact that this person has done it. . . almost like makes it an acceptable form of death. . . so that for me is how it's sensationalised as a method of death. (Irene)

The experiences outlined by our participants above demonstrate the danger in romanticizing suicide deaths. Suicide becomes an alluring method of escape from the mental anguish one may be suffering. These fantasies, that through suicide one becomes missed and legitimized as a great person, may influence the decisions of vulnerable individuals who encounter them, who may not otherwise have been exposed to them were it not for social media.

Negative Comments

Participants in Heffer et al.'s [24] research described being highly impacted by negative comments online in the aftermath of a suicide; this was identified as a potential contributor to suicide contagion. We found this to be consistent with our data; a single comment has the power to impact a whole community.

In this extract, Bridget reflects on how difficult it is not to dwell on a negative comment, even if it is outnumbered by positive ones:

There was an abundance of lovely comments. . . . but you don't focus on the hundred nice ones, you focus on the one that's nasty. (Bridget)

Alison observed the destructive effects of even one insensitive joke in relation to the suicide of a young person:

A boy who. . . posted a comment. . . and it caused riots, and I mean riots. . . it was very, very aggressive. . . and insensitive comments. . . they [young people] didn't have control over their emotions. (Alison)

This was one example of online discourse spilling into physical altercations.

Bridget observed aggression, conspiracy theories, and the attribution of blame being aired on the public forum; she sought to control the information in order to stem the destructive impact it would cause to others:

It almost goes into overdrive. . . they were angry . . . and wanting to put things that are not correct on there. . . it was almost like we had to become a filter for them and stop them just expressing themselves on there because it wouldn't have been appropriate. (Bridget)

These examples emphasize the need for control over the narrative. Frequently, a lack of control is displayed, with emotive and dramatic language being deployed which escalates the potential for distress:

You can't control it. . . it can come from anywhere. . . A relatively recent example where parents didn't want anything on social media but. . . . The child's friends had put lots of stuff on social media. . . . It's more than complicated. . . . You just can't control what comments are on there. . . when they are out in the open and not in closed forums. . . there's a real danger of. . . sabotage at times That's really really really difficult. . . in terms of understanding what that long term impact might be. (Peter)

One negative comment can be all it takes to catalyze fierce conflict. Louise talks about how this conflict is made a spectacle in the online community: "What an absolute shitstorm." This would be very unusual in an offline context, but our data implied it to be commonplace online:

People are playing out arguments that don't need to be seen by everybody. . . you might have hundred people looking at it, judging. . . feeling like crap because they've got into something on Facebook that they weren't expecting. (Elizabeth)

Some participants in Heffel et al.'s [24] study who were close to the deceased reported feeling angry at others for constantly posting on the deceased's Facebook page; some participants found constant reminders distressing and others questioned the sincerity of grief expressed by individuals who were not close to the deceased. They attributed this to attention seeking. Conversely, participants who

were not close reported using social media to learn about the deceased and searched the deceased's list of online friends to identify peers who might know more about the death. We found similar instances of this disconnect in expectations and norms regarding appropriate expressions of grief and shock online in our data. The disconnect in how attention-seeking behavior is construed by others can mean anger for those who see strangers comment on their loved one's death, while those who seek support through actively commenting can instead be antagonized. Either way, both are negatively impacted.

Implications for Postvention

It is now widely accepted that sensationalist forms of media coverage of suicide and suicidal behavior can trigger further suicides [30]. This phenomenon, described variously as copycat suicide, suicide contagion, imitation, or transmission, has been traced as far back as the 1700s. Known as the *Werther effect*, its name was inspired by Goethe's 1774 novel *The Sorrows of Young Werther*, in which the main protagonist in the story takes his own life due to a failed love affair. According to Phillips [31] and Stack [12], the novel was banned in several European locations and believed to be responsible for imitative suicides in Italy, Leipzig, and Copenhagen.

Suicide contagion can spread through a number of mechanisms, such as altering social norms around suicide, identification with an individual with similar characteristics or circumstances, or the implicit suggestion of suicide as a viable solution to problems. Such mechanisms are supported by social learning theory, which posits that behavior is learnt by observation of others [8, 17]. In general terms, the greater the coverage of a suicide story, the greater the chances of finding a "copycat" effect [12].

Knowledge and understanding of the Werther effect and suicide contagion have influenced the creation of guidelines for media regarding the safe and responsible reporting of suicide stories. More recently, increasing evidence has drawn attention to positive roles that media can play in suicide prevention [26]. The Papageno effect refers to the effect that mass media can have by presenting non-suicide alternatives to crises. Named after a lovelorn character from Mozart's eighteenth-century opera *The Magic Flute*, Papageno was contemplating suicide until other characters showed him a different way to resolve his problems. When Papageno fears that he has lost his love, Papagena, he prepares to kill himself. But three boys save him at the last minute by reminding him of alternatives other than dying. Neiderkrotenhaller [30] suggests that media can make a very relevant contribution to suicide prevention by maximizing reporting on how to cope with suicidality and adverse circumstances.

Media guidelines for safe and responsible reporting of suicides have been available for a number of years, including most prominently those produced by the World Health Organization internationally [32, 33] and Samaritans in the UK [34]. Generally, guidelines aim to encourage responsible reporting by reducing content that romanticizes, glorifies, or sensationalizes a death by suicide and prevent exposure to

content that might be triggering, such as overly simplistic explanations for the suicide and detailed descriptions of the method and location of death.

The need to promote responsible portrayal of suicidal behavior in England is a core part of the government's suicide prevention policy [4]. Despite this policy, and attention and campaigning to raise awareness about how media reporting can influence suicidal behavior, adherence to these guidelines is voluntary for reporters, and uptake of recommendations remain limited [17]. The media in England continue to publish sensationalist stories of suicide deaths. In some of our cases in our recent interviews, local media did not adhere to media guidelines. For example, stories about suicide deaths supplemented with invasively sourced photographs were publicized, and these were seen to accelerate social media use.

A key barrier to widespread voluntary uptake of media guidelines on responsible reporting, according to Sumner et al. [17], is that more sensational content is perceived to be more engaging to readers and this enhances publisher visibility and engagement – a point noted also by some of our participants, who reflected on the commercial motives of media conglomerates which run counter to safe and responsible reporting. According to Sumner et al. [17], no empirical information exists on actual influence of adherence to safe reporting practices on reader engagement, which could also be seen as another barrier.

Existing guidelines for managing media responses do not prompt affected communities to consider the role of communication technologies such as social media on suicide contagion. Sumner et al. [17] argue that guidelines, which were developed primarily in the era of print media, would benefit from adaptations to reflect evolving changes in media consumption behavior. This has not yet been achieved, but some inroads have been made. For example, revised guidelines have recently been published by Samaritans in the UK [34]. For the first time, these guidelines acknowledge the role of social media by advising journalists to treat social media with particular caution, suggesting it is safer not to open comments sections on suicide stories and to give careful consideration to the appropriateness of promoting stories through push notifications. It is acknowledged that sharing suicide stories on social media can increase the risk of sensationalizing a death. Samaritans have also recently published industry guidelines for sites and platforms hosting user-generated content to provide best practice principles for managing self-harm and suicide-related content online [35]. In Australia, guidelines have recently been developed by Orygen [36] to help young people communicate safely about suicide on social media. These include guidance on responsible use of social media in the aftermath of a suicide.

While these examples represent significant progress, more needs to be done to ensure that guidelines are up to date, understood, and adhered to. Historically, it has been difficult to urge the media to adhere to the guidelines, and this is an ongoing challenge. In order to counteract this, we suggest that postvention services can help manage the spread of information on social media that occurs in the wake of a report of suicide by print/news media. Our work points to important, practical ways in which postvention services can utilize our emerging understanding of the role of online communication in the aftermath of a suicide.

All postvention services should develop and implement a clear media strategy that is geared towards suicide prevention. The strategy should be underpinned by two fundamental considerations:

1. Measures to eliminate potential sources of contagion or increased distress from exposure to social media content in the aftermath of a suicide.
2. The prioritization of working with family and next of kin at the earliest opportunity.

We recommend that postvention services and other community agencies supporting those affected in the aftermath of a suicide proactively establish mechanisms to monitor social media and local media responses. Part of the strategy of working with families would be to help families write press releases and statements for the media and offer guidance in how to deal with social media and how (or whether) to memorialize the deceased online.

The immediate family have to be made aware, very quickly. . . the people affected. . . need to be careful on Facebook in the first instance. . . be prepared for. . . the blast of it. . . you have to make them aware that that sort of thing does happen. . . it's suicide itself that brings that out. (Cheryl)

Robertson et al. [25] suggested the monitoring of social networking sites by postvention services might allow detection of conversations or posts that might give cause for concern. Once identified, there needs to be an intervention to close down arguments and shield people from accusations of blame, insensitive comments, and the potential glorification of death by suicide. Our participants conveyed a strong sense that families should have control of the emerging narratives on social media. Postvention services have a role to play in helping to (re)gain this control.

In the first instance, we recommend postvention services implement a strategy that includes flooding social media with “cookie cut” statements that ask users to demonstrate respect and empathy and to pause and consider (“double think”) how their comments might impact on others before posting. This consideration for others was called for by several of our participants as a way of preventing the spread of rumor, misinformation, and the subsequent negative impact:

Make people kind of think about what they're going to post. . . respecting that person and the family at the moment... help people double think about what they're going to post. (Alison)

In addition, the Papageno effect should be considered. Reporting on how to cope with suicidality and adverse circumstances, using examples of lived experience, may be an effective component. The “cookie cut” statements could be accompanied by stories of hope and resilience in the aftermath of a suicide, highlighting a suicidal crisis as a temporary phase of despair which can be alleviated. This in turn could lead to a posting from the service to remind people they are there to help if needed. Services could also share posts that link people directly to further resources and information about suicide prevention: how and where to access appropriate support.

Although there is still lack of research evidence of protective effects [30], there is reason to be optimistic that this strategy will work. For example, Sumner et al. [17] found that closer adherence to safe-reporting practices was associated with a greater likelihood of an article being reshared, a finding that runs contrary to popular perception. Our previous work suggested the same, with details of available support services also being more likely to be shared [22].

Participants in our research instinctively used social media to raise awareness and campaign for suicide prevention in the name of their lost loved ones, which can be seen as an implementation of the Papageno effect. We saw examples of suicide-protective effects and how Facebook can be instrumental in decreasing the likelihood of suicide contagion if sites are utilized in this way [22]. It can help create a more positive legacy for the deceased and their family.

Heffel et al. [24] observed that some participants found constant reminders of the suicide distressing, suggesting it would be better to block or remove the page. DeGroot [29] recommends that site administrators take advantage of the privacy settings offered by Facebook to eliminate the presence of “emotional rubbernecks” (216). Similarly, our data found some examples of people autonomously making private groups in order to prevent unwanted, distressing, and triggering content:

Social media page. . . which is privately run. I think that’s probably the best way to keep it controlled on social media and not let it. . . get chaotic. (Alison)

More users should be aware that this control exists and know how to implement it. We recommend that postvention services offer guidance on how and when to navigate privacy settings, turn comments off, and create private groups.

Finally, postvention services can proactively campaign for clearer rules regarding page use and call for clearer processes that allow users to make complaints to social media when these rules fall short. Submitting complaints to Facebook in particular can be problematic; policies change frequently, and the legal framework around them has been difficult and patchy [37]. Experiences of our interviewees include a complaint to Facebook from a mother that her son had been memorialized without her knowledge; her complaint was met with an automatic reply referring her to Facebook’s terms and conditions. Postvention services could help navigate these processes, easing the burden from distressed families.

Conclusion

Exposure to suicide via social media increases the number of people previously estimated to be impacted by a death by suicide. Social media has overtaken traditional media in its reach and ease of access to information. Traditional media itself has been transformed by the introduction of instantaneous and interactive sharing of information created and controlled by anyone; by interacting with news information rather than passively consuming it, individuals spread the story further by sharing it and generate content by commenting on it.

Madianou and Miller [38] refer to polymedia, which is described as both a product and process; consumers of content are at the same time producers of content [17], and anyone can contribute, acting interchangeably as producers, audiences, and critics. To understand how media exposure to suicide influences and impacts on others in a “polymediated age,” it is important to take into account the many forms that media take and the many different interactions we can have with them. Therefore, as online social networks expand and the number exposed to suicide continues to grow, there comes an urgent need to understand and recognize the multiple ways in which everyone is impacted. Current understandings of the impact via media exposure fail to account for the globalization of communication made available by new technologies. Existing media guidelines also fail to account for the role of interactive digital media in suicide contagion.

In this chapter, we have highlighted that exposure to suicidal content via social media in the aftermath of a suicide can be both harmful and helpful for those affected, but the impact and effects of these practices are not yet fully understood. If we are to support those bereaved and affected by suicide who use social media, we need a thorough understanding of how this medium works; why people use it; who engages in these practices; when and where they emerge; the effect on the immediate and wider community of users; and how digital networks operate in these contexts for different communities. We have paired existing literature with some emerging findings that point to the negative impact and potential for triggering distress and contagion. Such work indicates that speculation and emotional outpourings shared online via social media can easily be misinterpreted and misreported, wrongly repeated as fact, and spread without due consideration for bereaved or vulnerable people.

Examples like these suggest a need for proactive monitoring and moderating of comments to safeguard against harmful, distressing, or triggering posts and to protect the privacy of individuals. The Papageno effect highlights potential benefits of media discourse on suicidality in contrast to the harmful Werther effects. Postvention services can play an important intervening role here by working with the bereaved to promote positive content on sites where online activity is creating negative impact. Robertson et al. [25] pointed out that the globalization of new media technologies makes the process of identifying others who may be at risk increasingly difficult. At the same time, however, we propose that the technology which causes the problem can also provide the solution. Social media presents an opportunity to reach some of those who are exposed and at risk; it provides a mechanism for postvention services to focus their efforts at critical points, delivering targeted, rapid support and helpful information to very large numbers of people.

This chapter has provided some insights into the role of online communication in the aftermath of a suicide and the impact of exposure in this way. In the world of the new media, we are all consumers and producers of media; this must be responded to with expanded efforts to educate all individuals on suicide prevention strategies. Much more research is required to further our understanding and update the media guidelines which will help reduce the risks of contagion. As the behavior by which users consume media is ever-changing, and social media brings suicide closer to all

of those in its vast userbase, suicide prevention becomes a responsibility for everyone. Suicide prevention is everyone's business.

Abstract

The relation between print media and suicide is still a major issue. There is a difference between radio and TV news because it is a document that can be read, reread, duplicated, and found anywhere privately or in public with text and pictures.

To date, suicide cartoons impacts, with often dramatic characteristics, have never been discussed.

Pictorial reports may have various effects and consequences. They can be as well:

- Informative = neutral, giving simple information
- Preventive = positive for suicide prevention and postvention
- Provocative = negative with contagious risks

Historical Recollections and a Current Issue

Many of us involved in suicide prevention and suicidology research have been by experience confronted with this dilemma.

The media have been accused of promoting suicide instead of preventing it.

News is mixed with a variety of sensorial information which can be very impressive and shocking.

The action is only postventional and that is, in fact, the basic question.

But is there a difference between print media and other media? Is print media's influence the same as other media?

Radio and TV are newflashes. Print media is a tangible document that can be read, reread, duplicated, and found anywhere privately or in public (offices, hotel lobbies, airports waiting rooms) with text and pictures.

Other questions are [3]:

1. Are they really responsible for increasing suicide?
2. What can be done to improve the relationship between suicidologists, health professionals, and media?
3. Can media be educational?
4. Is it a fact of modern society or not?

Many Studies Have Concluded That Media Could Be Considered Responsible for the Increase of Suicide [11, 12]

Jerry Motto, in a controlled study performed after his 1967 report on the role of the press [10], looking at the effects of a press strike in Detroit, concluded on the negative influence of media suicide. He declared: "a systematic effort is called for to eliminate emphasis in the press on the sensational details of suicide behaviours."

Later on, in 1992, David Phillips went further in his analysis and wrote: "Research suggests that one of the factors leading a distressed individual to suicide is the publicizing of model suicides in the mass media" [13].

It may be difficult or adventurous to be so clear since there are many other factors such as technical factors.

There is a difference if suicide is reported on the front page or in a headline, with or without a picture, glorifying the act or being outrageously sensational.

There is also a clear fact: Print media are frequently more interested in reporting the suicide of celebrities than noncelebrities, except perhaps in case of particularly unusual methods or in unusual circumstances.

A French suicidologist told me once that depending on whether the person is famous or considered a delinquent or rogue, the way the suicide is reported is different. The first ones are presented as having put an end to their lives, died by their own hands, or taking their own lives and the second to have committed suicide.

A rather ambivalent attitude is when print media reports collective suicide like the **Guyana massacre** in 1973 (913 deaths) [5], the Heaven's Gates members in California (39 deaths) in 1997, and the Solar Temple in France, Switzerland, and Quebec (69 deaths) in 1995, all equivocal suicides or deaths, which can be interpreted more like a mass homicide than a collective suicide. As a matter of fact, the impact on society is not clear.

Print media have, as said before, been accused to influence and create imitation and contagion of suicide.

Everybody knows what the Werther effect is [8].

Usually, the press answers or protects itself behind the "principal" shelter of free press or liberty of the press to inform the public of whatever happened with no specific obligation of control of what the news will produce or create.

Quite often, reporters follow their own fantasies, citing incomplete information recuperated during interviews and even in scientific meetings.

It may be argued that this is a deviation of the information, which alienates reflections on suicide phenomena based on ethics and science.

A former UNESCO report declared that the selection of information is based on a desire to disturb rather than to enlighten.

Therefore, a print report can have a positive influence as well as a negative one, seldom neutral, or purely informative.

An interesting study made in Turkey in 1938 by F. K. Gokay must be mentioned. It discusses the effect of a law voted in 1931, prohibiting any report of suicide in the press [2].

The study showed a decrease in the suicide rate, which appeared to be temporary, but during a period of socioeconomic turmoil from 1916 to 1936.

The author wrote: "What is the use for society to reveal the life of an individual in despair, tortured by thousand pains, and to expose him in the newspapers in a column with exaggeration and emphasis."

A summary of his conclusions could be: "It is the duty of specialist to know and take necessary measures to prevent indiscretion using preventive and educational publications. I am utterly convinced that this is not against freedom of the press. It concerns the life of a whole society."

This question of a free press reached its peak when suicide manuals were published.

Herbert Hendin, myself, and a few others have been fighting against this production of suicide books:

- In France : Suicide mode d'emploi (Suicide How to make it) Cl. Guillon. Y Le Bonniec. Editor A Moreau 1982
- In the USA : Final Exit, Derek Humphrey, Dell NYC, 1991

In 1984, I was invited to present a lecture at the French National Academy of Medicine answering this question: "Is suicide prevention still possible in France since the authorized publication of the book entitled: Suicide, how to make it – History, techniques, news?" [14–16].

At the time, in France and most other countries in the world, there were no laws able to control or prohibit those publications.

It took some time, because of a political dispute, to have at last in December 1987 a law against provocation to suicide, prohibiting publications promoting suicide.

It has been included in the French Penal Code.

It has been demonstrated how provocative this publication had been, influencing suicide rates in France. Following an exchange of correspondence with Editor T. Maltzberger in *Newslink* (1992), journal of *AAS*, about the publication of *Final Exit* in the USA, I suggested that:

"The American Association of Suicidology should not limit its action to gun control; it should address itself to book control as well."

In 1994, P. Marzuk et al. [9] compared suicide rates in New York before and after the publication of *Final Exit* in the USA and studied the methods suggested in the book.

It shows an immense increase of 30.8% of suicide by asphyxiation with plastic bags but no clear effect on the suicide rates.

Print media are certainly dramatically responsible for promoting suicide when publishing such manuals available in bookstores. They are different from manuals given to members of "dying with dignity societies."

To quote H. Hendin (1982) [4]:

They are not merely distributing "how to do it" information. They are the avant-garde of a larger attempt to seek social approval and institutionalisation for suicide.

Strangely, literature never mentions suicide cartoons. It is a rather dangerous mockery. Can anyone make a joke of such a dramatic event?

It is for some more provocative than preventive and may produce ambivalent fantasies and disturbing thoughts.

Therefore, What Can Be Done?

There Is a Need to Improve the Relationship Between Mental Health Professionals and Suicidologists with Media Professionals

In 1994, the Centers for Disease Control and Prevention (USA) first established recommendations, which are summarized as "guidelines for the reporting of suicide" [1].

Another Point

There is an ethical dilemma with the overacting media. But there may be also an ethical issue with mental health professionals giving interviews and their opinions on suicide without even having studied or knowing the case.

In 2002, in Madrid, WPA presented a declaration on ethical standards for psychiatric practice. Point 6 concerned psychiatrists addressing the media [20].

The Education of Media Is Essential. But Is It Possible?

In 2000, the World Health Organization with the international network for suicide prevention published a monograph entitled “Preventing Suicide: A Resource for Media Professionals” [19].

I had the privilege to translate it into French and to include a “translator note” where I indicate the proposal to initiate a “council of ethics for media” enabling to control, for instance, publication and interpretation of the media which unfortunately does not always fully or clearly report interviews given by mental health professionals.

I was told it was a splendid idea but impossible to put into act [7].

Last Interesting Point: “Is It a Fact of Modern Society?”

In a commentary published in the journal *Suicide and Life Threatening Behaviours* in 1996 (the Kurt Cobain Suicide Crisis), journalist Steve Knickermayer wrote:

Back in the 1950s, journalists did not report suicides in the newspaper [...] but journalists standards have changed overtime as society has changed [...]. When speaking to a reporter one should be careful about one says. One has to be especially careful when talking about life and death situations [6].

However, Reporting Suicide Can Help to Prevent Future Suicide

It is a postventional task as said in the introduction.

David Phillips also wrote in his study: “Modeling processes can lead ambivalent individuals towards suicide or towards alternatives.”

An alternative to suicide can be reported by the media. The best example was given by the suicide of Kurt Cobain when the entire media network confronted by the despair and anguish of a large number of youngsters collaborated with the suicide prevention network, not only in the area of Seattle where it happened but also all over the USA [6].

Print media are able and have to be encouraged to publish a list of resources in suicide prevention, lists of centers, and a message for a better life.

Conclusion

Print media can indifferently be:

- Positive for suicide prevention
- Negative by promoting suicide
- Neutral by giving straight controlled information [17]

Print Media and Suicide – awarded best scientific poster in 2010 at the 13th European Symposium of Suicide and Suicidal Behavior (Roma, Italy)

This poster contained various portrayals protected by copyright.

Another remark: Internet technologies can be considered as an equivalent to print media, but by providing accessibility, it adds a risk factor (cybersuicide) [18].

Abstract

The literature on suicidal behaviors in sex workers is still quite scarce worldwide. The few existing literature seldom focus specifically the research in suicidal behaviors, being these only one of the questions in larger studies, focused mostly in mental health or sexually transmitted diseases. This scarcity of literature is in part caused by the double stigma regarding suicidal behaviors and mental health on one hand, and sex work and sex workers on the other. In fact the stigma on sex work is what in part justifies the different regulatory models concerning sex work and therefore the different working conditions that these women live.

Nevertheless the few published studies, all seem to indicate an elevated risk of suicidal behaviors in these women, when compared to the general population in the different countries from where the studies are original.

To the best of our knowledge this is the first effort made to propose prevention strategies specifically for sex workers.

Keywords

Sex work · Sex worker · Suicidal behavior · Suicide Prevention

Introduction

Sex workers face multiple vulnerabilities, such as pressing economic needs, substance misuse, mental health problems, victimization, lack of social support, and in some countries they also face criminalization of their work. We know now that suicide behavior is yet another vulnerability that we should take into consideration when it comes to planning some kind of intervention aimed at this vulnerable and stigmatized group.

The objectives of this chapter are, for one side, to present the different studies regarding suicidal behaviors in sex workers and on the other to propose strategies aimed to reduce the prevalence of such behaviors in this vulnerable and stigmatized group.

Suicide Prevention in Sex Workers

The research regarding suicidal behaviors in marginalized or hidden populations, of which sex workers are a part of, is an emerging field of study, but the existing literature is still quite scarce. However, there is some evidence that sex workers are a group that might have a high risk for suicidal behaviors [6, 41].

Suicidal behaviors can encompass a complex and wide variety of behaviors as well as their outcomes. In this chapter, we adopt the perspective that considers suicide attempts and self-injury behaviors, including self-cutting, self-poisoning, and other types of intentional self-harm regardless of the reasons and/or the degree of suicidal intentionality [17].

Considering that this chapter aims to discuss the prevention of suicidal behavior in sex workers, it is necessary to better clarify the different types of sex work, as this chapter will focus only on one of the types of sex work, prostitution. It's therefore important to make a distinction between prostitution and other types of sex work (which includes activities such as prostitution, pornography, striptease, erotic dances, and erotic phone calls [23]. All of these activities have in common the goal of getting some type of profit and the fact that the object of the exchange has a sexual nature [31]. This description by Oliveira shows us just how difficult it is to establish clear and unambiguous boundaries between prostitution and sex work [16]. One of the ways to overcome this difficulty is to assume both terms interdependently, assuming that the limits of sex work are vague, and can range

from erotic exposures without physical contact with the client, to unprotected and high-risk sexual relations with multiple clients [16].

For the purpose of this chapter, the definition of sex work that we will use is of a commercial exchange, in which one of the parties brings an asset with economic value, in order to obtain a sexual interaction (genital, oral, anal, or masturbatory) with the sex worker. The sex worker may or may not obtain sexual pleasure and emotional involvement during this exchange [39].

Before looking at suicidal prevention strategies in this population, it is imperative to better know the prevalence of suicidal behaviors as well as the risk factors that the literature lists. Thus, considering that one of the most common forms of categorization of the sex work goes through the workplace of these women, and considering that there is a relationship between the place where sex work is performed and the characteristics of the person who does it [33], to better understand suicidal behaviors and their risk factors around each group of women, we'll consider each one separately.

Suicidal Behaviors in Indoor Sex Workers

A study carried out with a sample of 326 sex workers in Goa [37], found that 34.9% of these women reported suicidal ideation in the last 3 months, and that 18.7% reported suicide attempts in the same period. This research proposed as risk factors episodes of violence (mainly carried out by partners), the absence of offspring, mental health problems, and a more socially isolated work environment. The latter risk factor is explained as a result of a higher prevalence of suicide behaviors in women who worked in apartments, when compared to those who did it on the streets (OR 1.13 vs 1.38) [37]. There are two aspects that should be highlighted in this investigation. On one hand, unlike most studies, this research finds a higher prevalence of suicidal behaviors in indoor settings rather than in outdoor settings. On the other hand, its authors propose as explanatory factors for these results a greater social isolation, less social support from peers, and, lastly, a lesser sense of collective identity [37].

An investigation carried out in China, among a sample of 454 indoor sex workers in Guangxi, states that 8.4% of the women interviewed reported at least one suicide attempt in the past 6 months [43]. Those results were higher than those found in other risk groups in China (for example, women between 15 and 24 years old) [43]. Within this sample, women with more years of school education and higher dissatisfaction with life had higher rates of suicidal ideation and suicide attempts.

The high prevalence of suicidal behaviors among these women, according to the authors, may be a reflection of fragile mental health, which may in turn be associated with the lack of other job opportunities, dissatisfaction with the work performed, and sexual coercion. Sexual coercion is, moreover, identified as a determining factor, both to the dissatisfaction with work and with the increase in the prevalence of suicide ideation and suicide [43].

A complementary approach is presented to us by another investigation conducted also in China, which refers to the existence of four statistically significant variables regarding suicidal ideation in sex workers, namely: dissatisfaction with life, abusive alcohol consumption, having been forced or tricked into commercial sex, and; having a stable partner [19]. Regarding suicide attempts, the statistically significant variables were related to: the existence of multiple stable partners, the existence of experiences of rape in the last 6 months, peer pressure to maintain in the sex work industry, and financial hardships.

A study conducted in Israel found a relationship between a high prevalence of occupational hazards in women who: work in brothels, are immigrants, started early in sex work, were victims of sexual abuse before the age of 18, work many hours a day, had a history of suicide attempts, and had symptoms of post-traumatic stress [7]. For these authors, suicidal behavior is just another aspect to be considered when concerning occupational risks, instead of considering that it's the risks associated with sex work that accentuate the risks of suicidal behaviors. This reversal of perspective may help to deconstruct the causal idea that suicidal behaviors are caused by sex work, thus contributing to mitigate the stigma associated with sex work.

This perspective, however, is not consensual, as we can see by the results found in a study that compares two samples of women who are drug users, in which one of the groups was constituted by sex workers. In this study they found a higher prevalence of suicide attempts, in the female sex workers [13].

An investigation developed in a rural area of India presents a disturbing perspective about indoor prostitution, since 92% of its sample reported a diagnosis of depression, and 57% had a history of suicide attempts [18], these values are quite high when compared with the results of other researches. For the authors of this investigation, exposure to episodes of violence, either in the workplace or in an intimate context, are related to a more fragile mental health [18].

In a study conducted in Zurich Switzerland, designed to assess the mental health of sex workers in that city, the authors distributed the sample into four groups, specifically: (a) Swiss born street prostitutes, (b) women working in cabarets, salons and brothels, of unspecific cultural background, (c) European foreigners working in apartments and, (d) non-European foreigners working in apartments. Among the four groups studied, it was the group of non-European foreigners who had the highest rates of victimization and the highest incidence of mental health diagnoses. Of these women, 73.3% had anxiety disorders, 46.7% were diagnosed with depression, and 40% had diagnoses of post-traumatic stress [35]. The lack of social support, as well as the legal situation in the country and therefore access to health services, appeared as determining factors in the high prevalence of psychiatric symptoms presented by non-European women who worked in indoor context.

In spite of the few studies found, there seems to be some consensus that more important than sex work itself, it seems to be the social environment, legal situation, and working conditions that have the higher impact on the rise of mental health problems and, more specifically, in suicidal behaviors. Only the investigations by Shahmanesh [37] and Rössler [35] seem to indicate a higher prevalence of suicidal behaviors in indoor sex workers, when compared with street sex workers.

Suicidal Behaviors in Street Sex Workers

Regardless of the context and the regulatory model of sex work, there is a wide range of literature that considers street sex workers, as those who occupy the lowest level in the hierarchy of sex work [4, 12, 30, 31].

Therefore it is important to know more about suicidal behavior in this group of women.

There is little research that focused only in the study of suicidal behavior in street sex workers. However, it is noteworthy the existence of literature that addresses the health of these women and that concomitantly refers to suicidal behaviors.

An example of this is the work developed by Vanwesenbeeck [42] in the Netherlands, which states that women who had traumatic experiences in childhood later presented a higher prevalence of anxious depression, as well as a higher level of aggression, both hetero-directed as well as self-directed, resulting in a higher prevalence of nightmares, distrust, and suicidal ideation.

In a sample of women undergoing methadone treatment, those who were also sex workers had higher levels of depressive symptoms and psychological distress [10]. In previous studies, the same authors had highlighted the importance of developing further investigations, in order to better understand, whether the psychological suffering presented by sex workers was a precursor or was caused by sex work, and how sex work, depression, and psychological suffering were correlated [9]. The illegal nature of sex work and the resulting stigma for sex workers has been suggested as being able to accentuate psychological suffering [11]. Therefore psychological suffering in these women may be associated with the stigma resulting from the illegal nature of sex work, in countries where sex work is illegal, thus contributing to greater psychological suffering in sex workers.

Although the existence of a myriad of psychological problems associated with sex work, such as depression, schizophrenia, or suicidal tendencies, has already been presented by several authors, that has been done without a real discussion about possible explanatory causes [12].

Focusing now on these women's suicide attempts, these appear to be quite high. According to Johnson (1992 cit in [12]), about 50% of all sex workers, at some point in their lives, made at least one suicide attempt.

Another study of qualitative nature and with the aim to analyze the relationship between suicide and sex work in adolescents shows that in their sample 76% had already at least one suicide attempts [22]. This study, focused on the emotions and feelings of these youngsters associated with their suicide attempts, highlights that at the time of the suicide attempt, these young people had mostly feelings of depression, isolation, rejection, betrayal, lack of control, and low self-esteem. For these authors, the precipitating factor that led to the attempted suicide could be a "bad job." This "bad job" could have several meanings, namely, working and not being paid, carrying out a long work or one that required too much effort, being physically or sexually assaulted, or being subjected to degrading comments. It is important to note, however, that the source of stress and emotional suffering that was at the origin of the suicide attempts in these samples was not exclusively related to their professional sphere. The relationships

maintained with their partners emerged as an equally relevant factor for this consideration. About 70% of their sample reported that the existence of problems with their partners was an important source of stress and emotional suffering [22].

A Chinese investigation with 454 sex workers found a prevalence of 8.4%, with regard to suicide attempts, in the past 6 months. This same study points out that, for the same period of time, the prevalence of suicidal ideation was of 14.2% [19]. Although the suicide rate in China is considerably higher than the Global suicide rate [32], the rates presented by this sample of sex workers are higher than those found in the general Chinese population ([19]).

Our own research, carried out in Portugal, focuses on the prevalence of suicidal behavior in street sex workers.

When regarding the prevalence of suicidal ideation, we saw that 46.15% of the interviewees presented elevated levels of suicide ideation, scoring 41 or more points in Reynolds Suicidal Ideation Questionnaire [41].

In this sample, 44.2% of the sex workers reported at least one suicide attempt, and those who reported suicide attempts, 30.4% had 3 or more attempts [41].

Our investigation seem to indicate that more than the professional sphere, it is the personal, familiar, and romantic spheres that appear to have a predominant weight for the understanding of suicidal behaviors in sex workers. Of the women of our sample, 65.2% reported that the existence of conflicts with family members was at the origin of their suicide attempts. Mental health problems, such as depression and stress (30.4%), or episodes of violence resulting from professional activity (4.3%), arise after family issues for these women [41].

If, as a group, sex workers seem to have more somatic symptoms and psychosocial problems, we should not, however, regard sex workers as an indivisible reality, since their experiences are diverse [42]. The way in which sex workers perceive their work, as well as the duration, frequency, severity, and perception of exposure to risk factors will determine the level of deterioration of their physical and emotional health [46].

Common Risk Factors

Despite the scarcity of investigations on suicidal behaviors in sex workers, we cannot avoid noticing that both suicidal behavior in women as well as the entry and maintenance of women in sex work, share a myriad of risk factors that are commonly associated with both situations. This fact led us to focus our attention on this reality, aiming at the development of strategies that allow us to reduce suicidal behaviors in these women.

With the exception of low academic qualifications [42, 45] and low income [28, 30, 31], which the literature only presents as risk factors for street sex workers, the remaining risk factors, such as the pressing economic needs [1, 4, 19]; the consumption of psychoactive substances [19, 38, 44]; the existence of mental health problems [28, 37, 42]; episodes of childhood victimization [2, 7, 38]; the physical and sexual violence by peers [5, 42, 44]; and the low social support [20, 37, 42] are transversal to the different working contexts of sex workers.

The literature on suicidal behaviors in sex workers is based on some limitations.

Firstly, they rarely focus specifically on suicidal behaviors in sex workers. They also tend to aggregate together all types of sex workers, without making any reference to their workplace, seeming not to recognize the differences between the different work contexts. For last, they only explore superficially the risk factors inherent to suicidal behaviors. The published research do not seek to understand, in depth, the history of suicidal behaviors of these women (e.g., the reasons behind an attempt, the history of suicidal behaviors in the family), that could be preponderant to outline and implement prevention strategies.

Suicidal Behavior Prevention

The few literature available, regarding suicidal behaviors in sex workers, estimate a higher prevalence of suicidal behaviors in these women when compared to the general population [13–15, 40, 41]. It has been recognized that, alongside security forces, inmates, LGBT people, and homeless, sex workers are a specifically vulnerable group regarding suicidal behaviors [36]. Thus, the prevention of suicidal behavior in these women is an important challenge for public and community health.

In our own country, although suicide behaviors in sex workers have been recognized as a problem, in the National Suicide Prevention Plan [8], there isn't to date, any project implemented with the aim to prevent suicide behaviors among sex workers.

Suicidal Behavior Prevention in Sex Workers

Despite the better knowledge about suicidal behaviors, and its prevention nowadays, it hasn't necessarily implied a decrease in the number of deaths by suicide worldwide, which shows us how complex and challenging this task is.

If the prevention of suicidal behavior is generally a herculean task, it's even more defying when aimed at especially vulnerable groups, such as sex workers.

Therefore, we propose a set of strategies, which in a concerted manner, may help to mitigate the emotional suffering of these women and consequently the prevalence of suicidal behaviors.

Training on Suicidal Behaviors to Harm Reduction Services

The contact of NGO's that develop work in the area of Harm Reduction with especially vulnerable populations provides a unique opportunity, on the one hand, for the identification of risk factors, and on the other for referral to the health services [26].

It is not intended to transform Harm Reduction services and their technicians into suicide specialists; however, a more detailed knowledge of the risk factors as well as

of the existing resources in suicide prevention and treatment, together with the privileged relationship that these technicians have with sex workers, may improve the early detection of risk of suicidal behaviors.

The resource to these NGO's and technicians to the prevention of suicidal behaviors can be achieved through the application of a short training program, focused on topics, such as:

- Epidemiological data on suicidal behavior.
- Risk factors vs protective factors.
- Information about community resources to which the sex worker can be referred to, such as:
 - Emotional support lines.
 - Primary health services.
 - Suicidal prevention consultations.

Training on Suicidal Behaviors for Sex Worker's Peers

The use of peer-to-peer interventions has been extensively used with vulnerable and hard to reach consumers of psychoactive substances or sex workers [3]. The effectiveness of Harm Reduction interventions has been advocated by several authors [25, 34].

Latkin [25] suggests that peer-led interventions will be more effective than those carried out by professionals since:

- Peers are a more reliable and influential source of information since the subjects of the intervention identify with their peers, due to a greater cultural and experiential proximity.
- Peers in their interventions use already established networks to share information and advice. Peers are also able to reach individuals who remain less receptive for professional's interventions.

Despite the literature supporting the use of peers, namely, in the harm reduction in risk of sexual behaviors and in the reduction of syringe sharing among drug users, its effectiveness in reducing the prevalence of suicidal behaviors is not yet proven. However Mann and collaborators [26] refer that this kind of intervention increases knowledge and improves attitudes toward mental health and suicide. For this reason, we believe that it would be negligent if we did not propose the use of peer training in the context of the general effort to reduce the prevalence of suicidal behaviors in sex workers.

Providing Emotional Support Services

A recent systematic review, designed to assess the impact of telephone emotional support services, found a positive impact in the reduction of the levels of suicidal ideation both in the immediate as at short term, as well as an improvement of

depressed mental states, and a positive response from callers, namely, those who suffer from a chronic health problem [21].

Although the emotional support services may have some differences between them [27], they share a common basis of anonymity and confidentiality, which allows callers to speak without any kind of social pressure or fear of moral judgment. Being sex workers, and particularly subject to moral judgment groups [29], the reservation of the identity and the anonymity assume particular relevance for them.

Emotional support services can usually be done by volunteers or trained professionals [27]. Although the effectiveness of this type of intervention is not yet completely proven, these emotional support services can inform and refer to health services that can intervene in a situation of suicidal crisis.

Referral to Health Services in Situations of Suicidal Crisis

It is widely recognized that psychiatric disorders represent an increased risk for suicidal behaviors [47], and that psychiatric disorders are estimated to be present in at least 90% of suicides [26]. Untreated or undertreated depression even after a suicide attempt is a recurrent situation, therefore treating mood disorders and other mental health problems is a central component of a suicide prevention strategy [26].

It is important to note that although many countries have a free and universal National Health Service, the characteristics of this health services, combined with specific circumstances and the individual characteristics of sex workers, makes access to health often inaccessible or difficult for sex workers due to the way the services are structured [24]. It is therefore necessary to create priority access routes for sex workers.

transformational change, a suicide care model with specific practices for health systems to employ, and a movement seeking to make health care settings safer and more compassionate for people with suicidal thoughts and urges. Zero Suicide fills the gaps that patients at risk for suicide often fall through by using evidence-based tools, systematic practices, training, and embedded workflows. Continuous process improvement drives this model to ensure organizations deliver quality care, routinely examine outcomes, and remain committed to fidelity. Leadership that is dedicated to suicide prevention as a core responsibility of health care is critical. Health care programs that have implemented Zero Suicide are a version of high-reliability organizations (HROs) that via relentless quality improvement and attention to detail are able to perform high-risk work in complex domains without serious accidents or catastrophic events. The realization that suicide deaths for those under care is preventable, coupled with the availability of best practices and tools to implement these strategies, means quality and effective suicide care cannot be ignored. Included in this chapter is a description of the birth of the Zero Suicide model as a roadmap for health care systems, the rationale for the components of the model, the results of early adopters of Zero Suicide, and future directions for suicide care in health care systems.

Introduction

The dramatic and sustained increase in rates and numbers of US suicide deaths in this century is drawing attention. Each yearly report from the Centers for Disease Control (CDC) or the Veterans Administration strengthens the narrative about increased deaths and keeps suicide in the national conversation. The “deaths of despair” analysis by Case and Deaton [7] put a spotlight on the surging death rates from overdoses, suicide, and alcohol poisoning that has reduced overall life expectancy. And most recently, the CDC reported that rates of seriously contemplating suicide have increased dramatically during the novel coronavirus pandemic [18].

During the same period, efforts to prevent suicide have also expanded dramatically in the USA and abroad. The last two decades have seen the initial publication in 2002 and later a revision in 2012 of the US National Strategy for Suicide Prevention, creation of a national suicide prevention telephone hotline, and designation of a single national crisis number – 988 – by the Federal Communications Commission. Additionally, in the last 20 years, grant programs specifically for suicide prevention and research were established at the federal level by agencies such as the Substance Abuse and Mental Health Administration (SAMHSA), National Institute of Mental Health (NIMH), Indian Health Service (IHS), and CDC, as well as the funding for a

national Suicide Prevention Resource Center (SPRC). Though this increased attention and spending over the past two decades has been substantial compared to the preceding decades, and has resulted in more compassionate and better evidence-based ways to approach the challenge of suicide, the scope and scale of organized efforts remain very small compared to the scope of the problem. To illustrate this, consider that suicide is currently the tenth leading cause of death in the USA at about 48,000 suicide deaths annually. A comparison of the US National Institutes of Health (NIH) research investments per fatality for HIV/AIDS compared to suicide finds spending of over \$100,000 per HIV death versus about \$2000 for suicide.

In this chapter, we review the development and spread of the Zero Suicide model – a systematic approach that aims for “suicide safe” care in health care systems. The Zero Suicide model emerged from the US National Strategy for Suicide Prevention in 2011 and is being implemented in whole or part throughout the world. We describe the results of early implementation and suggest opportunities for more widespread adoption of the Zero Suicide model. Broader adoption of Zero Suicide may be a key strategy to slow the increase in suicide, or even to reduce the rate, since most deaths are among people who used health care services, and Zero Suicide has been feasibly implemented while reducing deaths in a number of early efforts. Zero Suicide is at the tipping point. The realization that suicide deaths for those under care is preventable coupled with the availability of best practices and tools to implement these strategies means quality and effective suicide care cannot be ignored. Collaborative care and other models have opened the door to the recognition that the triple aim can be achieved (improving the experience of care, improving the health of populations, and reducing per capita costs of health care) by co-locating or greater intentionality in integrating medical with behavioral health providers since individual patients are complex and often multi-morbid. However, despite these advances, many health care systems have yet to prioritize suicide care. What follows is a historical record of the birth of the Zero Suicide model as a roadmap for health care systems, the rationale for the components of the model, the results of early adopters of Zero Suicide, and future directions for suicide care in health care systems.

Zero Suicide Model Emerges As Part of National Strategy for Suicide Prevention

A key part of the national infrastructure to bolster suicide prevention efforts was created in 2010 with the formation of the National Action Alliance for Suicide Prevention (Action Alliance) – a public–private partnership tasked with advancing and refining the national strategy. Over a dozen task forces were established early on by the Action Alliance to better understand and reduce suicide in critical but underdeveloped and somewhat poorly understood areas that were part of the first national strategy – public messaging, research, faith, workplace, American Indian/Alaska Native (AI/AN) communities, military, lived experience – as well as one task force tasked with critically examining suicide in the context of health care. The first national strategy omitted goals to reduce suicide in health care systems, mistakenly

assuming that health care was safe and effective for those entering with suicide risk. The Clinical Care and Interventions Task Force challenged that fallacy and aimed to examine whether health care could do better for those at risk for suicide. The task force effort revealed deficiencies in the identification and treatment of suicidal people receiving care within health care organizations and opportunities to improve that care based on emerging experience and research findings [10]:

- A great majority of people who die by suicide had recent contact with a health care program or provider – especially primary care, emergency departments, and mental health programs [42, 79] – highlighting missed opportunities to identify risk and provide relevant care.
- Health care does not systematically attend to suicide prevention: patients are not routinely or systematically screened, protocols and expectations for any kind of care that directly targets suicidal thoughts and behaviors are absent, and evidence-based practices are used inconsistently, if at all. However, the science of how to address suicide risk directly and based on evidence has improved considerably, and promising practices are now available.
- Health care professionals, including mental health professionals, are usually not trained to care for people at risk for suicide, and professional credentials do not require competence in “suicide care,” although suicidal people are sent to mental health settings. Too frequently, suicide risk provokes anxiety and avoidance in clinicians. However, promoting a culture of shared responsibility and providing quality training mitigates clinicians’ anxiety, allowing them to address suicide risk appropriately.
- A general fatalism about making a dent in the outcomes for those at risk for suicide persists. Promising approaches to suicide prevention in health care emerged in the last two decades, but they were new. Because of this, and since suicide prevention was not seen as a core health care task, they were not widely used.

The task force report states that “As major contributors to suicide prevention and intervention, public (including primary care, general medical care, emergency services and medical-surgical care) and behavioral health systems must make dramatic changes in how they perceive and address suicide” ([10], p. 8). This report highlighted the possibility that health care could and should uniquely contribute to suicide reduction in the USA, and thus new goal areas were included in the revised 2012 National Strategy: promote suicide prevention as a core component of health care services, and promote and implement effective clinical and professional practices for assessing and treating those identified as being at risk for suicidal behaviors [55].

A Set of Recommendations for Safer Care

The 2011 task force report, *Suicide Care in Systems Framework*, offered a synthesis of effective practices integrated into a roadmap for reducing suicide deaths in health care systems. The success of the US Air Force Suicide Prevention Initiative in the

late 1990s, in which the suicide rate dropped by one-third over a 6-year period [38], prompted the task force to shift its initial focus on better training for individual clinical staff to a systems approach. In 2012, David While, Harriet Bickley, Navneet Kapur, and others published research in the “Implementation of mental health service recommendations in England and Wales and suicide rates, 1997–2006.” Their findings also suggested systematic approaches that integrated evidence-based practices reduced suicides by 200 to 300 per year [80]. This research was making its impact at the very moment the task force was considering strategies for systematic, quality improvement approaches for health care systems.

A review of several health care systems, which had implemented elements of the approach revealed successes in reducing suicide attempts and deaths. In reviewing these initiatives, the task force found three critical factors common to all that led to their remarkable successes:

- **Core Values** – the belief and commitment that suicide can be eliminated in a population under care (a “boundaried population”) by improving service access and quality and through continuous quality improvement.
- **Systems Management** – taking systematic steps across systems of care to create a culture that no longer finds suicide acceptable, setting aggressive but achievable goals to eliminate suicide attempts and deaths, and organizing service delivery and support accordingly.
- **Evidence-Based Clinical Care Practices** – delivered through the system of care with a focus on productive patient-staff interactions. These methods (e.g., standardized risk stratification; evidence-based clinical interventions specific to managing suicidality, accessibility, follow-up, and engagement; and education of patients, families, and health care professionals) achieve results.

The task force offered a set of recommendations that outlined a vision for safer care. One recommendation was that organizations should take progressive steps to implement and measure progress with an ultimate goal of zero deaths among members/patients, thus laying the foundation for Zero Suicide as the call to action, as well as new nomenclature for this ambitious initiative. The Zero Suicide approach is several things: an aspirational goal designed to catalyze transformational change, a suicide care model with specific practices for health systems to employ, and a movement seeking to make health care settings safer and more compassionate for people with suicidal thoughts and urges.

The Zero Suicide Model

The Zero Suicide model operationalized the recommendations of the Action Alliance report. Many of the recommendations were based substantially on the Henry Ford Perfect Depression Care Initiative – an innovation which was at its heart a health care transformation effort [11]. Henry Ford’s Perfect Depression Care Initiative had an overall aim of rapidly achieving “ideal care,” which was defined in part

by an audacious goal to eliminate all suicides. The population served by Henry Ford Health System (HFHS) includes individuals with acute and serious mental illness whose hazard ratio suggests they are 12 times more likely to die of suicide than are those in the general population. Nevertheless, HFHS reported a 75% reduction in suicide for this population in the first 4 years of implementation and zero deaths during all of 2009. Over the period of implementation, the effort succeeded in reducing suicide deaths among a population under psychiatric care to about the level in the general population [14].

The early framers of the Action Alliance were focused not just on adopting a clinical package, but on emulating the Henry Ford approach to system transformation and change management. This meant making culture change and quality improvement core parts of the approach. Similarly, the task force report was informed by the successful suicide care effort by the Magellan Health managed care program in the Phoenix (Maricopa County) mental health system that emphasized basic training for frontline staff in working with suicidal people.

Thus, the Zero Suicide model is defined by a systemwide, organizational commitment to better suicide care in health and behavioral health care systems. The Zero Suicide model represents a culture shift away from fragmented suicide care toward a holistic and comprehensive approach to patient safety and quality improvement – the most fundamental responsibility of health care – and to the safety and support of staff, who do the demanding work of treating and caring for suicidal patients. Zero Suicide fills the gaps that patients at risk for suicide often fall through by using evidence-based tools, systematic practices, training, and embedded workflows. Continuous process improvement drives this model to ensure organizations deliver quality care, routinely examine outcomes, and remain committed to fidelity (see Fig. 1). Health care programs that have implemented Zero Suicide are a version of high-reliability organizations (HROs), that via relentless quality improvement and attention to detail are able to perform high risk work in complex domains without serious accidents or catastrophic events. Health care systems are starting to be comfortable with the language of HROs, and thus implementing safer suicide care practices is natural. Seeing suicide as a never event forces the organization to use best practices, apply continuous quality improvement, and emphasize reducing errors, while holding the system to account, not the individual.

Defining the Elements of the Zero Suicide Model

The Suicide Prevention Resource Center (SPRC) set out to operationalize the recommendations of the task force report so that it could be utilized by health care systems. This was done by better defining the model and offering guidance, tools, resources, and a robust, evolving online toolkit (Available at www.ZeroSuicide.com). Zero Suicide was framed as seven elements each emphasizing evidence for health care systems to adopt and that are to be used as a collective bundle (see Fig. 2):

Fig. 1 Framework for elements included in the Zero Suicide model

1. **LEAD** systemwide culture change devoted to reducing suicides and acknowledge that top leadership commitment and dedicated front line champions are both necessary for success. Defining suicide prevention and effective treatment as a core responsibility of the health care system is essential and needs to be communicated to staff, to patients, and to their families. All staff play an integral role in reducing suicide with deference to the expertise one holds rather than their rank or role, while the value of incorporating those with lived experience into leadership, governance, and care processes is crucial to success.
2. **TRAIN** a competent, confident, and caring workforce. Interactions with staff are a critical part of any patient experience. This is doubly true for many suicidal individuals who have had experiences with health care providers or interventions where their needs were not met, their suicidality not reduced, and worse, where they were stigmatized or traumatized. Providers can provide hope to patients and their families that their symptoms can be alleviated, with clear explanations of how this can be achieved. Most health care providers (psychiatrists, psychologists, nurses, social workers, physicians, etc.) never received suicide-specific training in graduate or medical programs, so it is foolish to expect that they

Fig. 2 The seven elements of the Zero Suicide model

would be aware of the emerging array of evidence-based suicide care practices [10, 57, 64, 68, 74]. Health care systems should ensure staff receive the tools and training to do this work and not assume that licensure equals expertise. Interactions with patients need to be person-centered, collaborative, and careful to acknowledge the ambivalence that patients contemplating suicide risk often feel. Understanding that ambivalence – the desire to find a solution to the intense pain they feel versus the innate human desire to live – is essential for any clinician working with a patient at risk of suicide.

3. **IDENTIFY** individuals with suicide risk via comprehensive screening and assessment [67]. Well visits involve routine screening for cardiovascular health by checking blood pressure and lipid levels [32]. Screening for suicide is comparably effective at identifying individuals with elevated risk, while predicting suicide risk by considering demographic factors such as age and sex is ineffective. Therefore, the use of a standardized screening tool, administered at every visit, will help to ascertain those at risk who might not otherwise be identified. For those who screen positive, the use of a standardized risk assessment tool and risk formulation needs to be conducted to determine the course of treatment and next steps [46, 51, 60, 67, 78].
4. **ENGAGE** all individuals at risk of suicide using a suicide care management plan that includes immediate safety planning with steps to reduce means of self-harm [70–73]. Once a patient is identified as at risk, creating a collaborative safety plan and facilitating lethal means safety by reducing access – with confirmation – to the lethal means during the period of acute distress needs to follow. Additionally,

patients and their families should be provided clear communication about treatment plans and the rationale for care, educated on the clinical workflows/suicide care management plan the agency is offering that will target their thoughts of suicide, and offered hope that care can be effective and recovery is possible. Similar to screening tools, safety plans should be reviewed and updated at every visit while a client is on the high-risk pathway ([6, 24, 27, 28, 30, 37, 43, 58, 63]; Suicide Prevention Resource Center n.d.).

5. **TREAT** suicidal thoughts and behaviors directly using evidence-based treatments. Research in the last 10–15 years has emerged to suggest that suicide can be targeted directly through treatments that focus explicitly on the suicide risk, both to keep patients safe and to help them to thrive. Randomized controlled trials have found that Cognitive Therapy for Suicide Prevention (CT-SP) [5, 69], dialectical behavior therapy (DBT) [40], and the Collaborative Assessment and Management of Suicide (CAMS) [16] all reduce suicide and suicide behaviors. Even brief interventions delivered during single in-person encounters are effective in reducing suicide behaviors [20]. It is essential that clinicians apply these techniques that are known to reduce suicide, but they must be trained in these modalities.
6. **TRANSITION** individuals through care with warm hand-offs and supportive contacts. As many as 70% of people who attempt suicide never attend the first mental health appointment or go beyond one or two visits [54]. There are barriers to attending appointments – childcare, travel distance to see provider, time off work, payment – but concern about whether treatment will be effective or the provider can actually help should not be a barrier. The period after discharge from a hospital or emergency department is a high-risk time for increased suicide behaviors and deaths [37]. Physicians and others responsible for care transitions can introduce clients to mental health providers (warm handoffs), call to remind them of appointments or see that they went and will continue to go, and send them caring and supportive contacts between appointments. Automated or low-burden phone calls from medical providers reminding people of upcoming appointments, follow-up calls after surgery from care coordinators or nursing staff, or even check-ins from physicians after a complicated appointment or new diagnosis are commonplace now. They improve compliance and commitment to care and reduce barriers to follow-up appointments. The evidence [73] suggests this works to reduce suicide as well [23, 37, 43, 44, 47, 50].
7. **IMPROVE** policies and procedures through continuous quality improvement, collect and examine data routinely, and maintain fidelity to the processes you are establishing for the system. Data-driven quality improvement is essential to ensure improved patient outcomes and better care for those at risk of suicide [10, 12, 26]. Specifying all aspects of suicide care in the clinical workflow and monitored in an electronic health record will provide necessary data to identify successes and failures in care. However, continuous quality improvement can only be effectively implemented in a safety-oriented, “just” culture free of blame for individual clinicians when a patient attempts or dies by suicide, which would include supporting clinicians and staff following the suicide death of a patient. In

a Zero Suicide approach, a data-driven quality improvement approach involves assessing two main categories: 1) fidelity to the essential systems, policy, and patient care components of the Zero Suicide model, and 2) patient care outcomes that should come about when the organization implements those essential components. Outcome measures are only one component of the data collected, as these data will help you understand what ultimately happens to those in your care but do not necessarily tell you about how effective your policies, clinical workflow, and trainings have been or how to improve [8, 12, 13, 36, 62]. The screening tools and high-risk pathway should be embedded as part of the EMR/EHR accessible to all clinicians and reviewed often for fidelity to the processes established by the health care system.

As illustrated above, there is evidence for each element of this model. Early implementation efforts, which we will summarize below, also demonstrate that the full model is effective. Recent research and experience at Zero Suicide sites also confirm that not all people at risk for suicide need or will even benefit from hospitalization or crisis services. Most individuals identified with suicide risk do not need to go to the hospital and instead can be managed with intentional, quality outpatient mental health care that is tailored to their needs and risks, with safety planning at each session, monitoring/supportive contacts during any breaks in care, etc. However, many providers still over-rely on sending patients to the hospital as a result of their own inexperience, poor suicide-specific education, and/or anxiety, which only compounds patients' trauma and distrust. Thus, along with the emphasis on treating suicide risk directly with evidence-based interventions, newer models of care suggest that treatment and support of persons with suicide risk should be carried out in the least restrictive setting. Interventions should be designed – and clinicians should be sufficiently skilled – to work with the person in outpatient treatment, with an array of supports, and avoid hospitalization if possible.

A “stepped care treatment approach” has been recommended for care of individuals with suicide risk [1]. In a stepped care model for suicide prevention, patients are “offered numerous opportunities to access and engage in effective treatment, including standard in-person options as well as telephonic, interactive video, web-based, and smartphone interventions (S225).”

Stepped care has been applied to a myriad of health and behavioral health issues, including substance abuse, depression, stroke, chronic illness, and insomnia, to name just a few. Stepped care involves delivering care such that less-intensive, often less-restrictive interventions are offered to patients wherever appropriate and then “stepped up” to more intensive services as clinically indicated. Patients at risk for suicide need to be engaged in an individualized, culturally sensitive manner that takes into account their needs and preferences in order to achieve the outcomes sought.

Zero Suicide, therefore, is a robust set of suicide-specific interventions administered systematically, routinely, and with needed training that when applied consistently and with fidelity, has the potential to reduce suicide deaths for people under care. Zero Suicide can also be described as a “stretch” patient safety goal that

galvanizes cultural change in health care organizations, catalyzing leadership and providers to relentlessly pursue perfection.

Early Adopters and Outcomes

The context of rising concern about suicide, the results at HFHS, and the development of effective, feasible treatments provided fertile ground for the development and uptake of Zero Suicide following the 2011 report of the task force. This report resonated with many advocates who sought improvements in preventing suicide in health care. Two organizations quickly committed to the work of fully developing and implementing the model. Centerstone is a large multistate nonprofit providing a wide range of behavioral health care services; the Tennessee operation provided comprehensive behavioral health services, including strong crisis programs. Under the leadership of the Vice President for Crisis and Disaster Management Becky Stoll, Centerstone Tennessee (TN) committed to fully implementing the model. In New York State, the Institute for Family Health provides integrated primary care and behavioral health services (and in many locations, dental services) in the metropolitan New York City area. At the Institute, Virna Little, then senior vice president of Psychosocial Services and Community Affairs, committed to serve as a second national prototype for Zero Suicide. Dr. Little had managed an early replication of the Collaborative Care model at the Institute and was experienced at driving behavioral health program development within a health center model.

Beginning in 2012, these and several other organizations began the work of providing better suicide care, using and shaping all the elements of the emerging Zero Suicide care model. Aspects of the model were also being implemented in Texas, Kentucky, Indiana, Oklahoma, and New York and were led by state suicide prevention coordinators, local and state mental health care departments, and a few health care leaders. SPRC convened these early adopters to refine the model, share lessons learned, and summarize their implementation efforts for wide-scale dissemination via the toolkit.

At Centerstone, in a population entirely under care for behavioral health diagnoses, the baseline rate for suicide before Zero Suicide implementation was 31 people per 100,000; the suicide rate 2 years into implementation dropped to 11 per 100,000 – a reduction of about 64%. Data analysis, as well as a focus on who to count, has been invaluable to Centerstone TN in supporting quality improvement. Initially, Centerstone TN found a 64% reduction in suicide deaths from October 2012 to February 2015; however, through their continual data collection and analysis, quality improvement staff detected an increase in deaths in the 12-month period between March 2015 and February 2016. Almost half (47%) of these deaths were among patients who had not been screened as having elevated suicide risk and who were receiving only brief (15–20 min) medication checks, rather than appointments that included counseling. Clearly, brief infrequent contacts were not sufficiently protective. In response, Centerstone TN developed a two-pronged approach. First, they developed a protocol for treating patients who preferred medication-only appointments. Second,

Centerstone TN created a guide for their medical providers to help them assess in what circumstances patients would be candidates for medication-only appointments. After these strategies were implemented, suicide deaths fell by 57% from May 2016 to June 2017. Clarity and definitions around who to include in the denominator has helped Centerstone TN better focus on the impact of their suicide prevention efforts (Becky Stoll, Centerstone TN, personal communication, August 13, 2020).

The Institute for Family Health, a network of community health centers in New York, monitors adherence to its suicide care protocol. For example, after a safety-planning template was embedded into the electronic health record and training and monitoring were provided, safety plan usage by primary care providers for patients with a positive suicide screen increased from 38% to 84% over 2 years (Virna Little, Institute for Family Health, personal communication, February 22, 2016).

Riveredge Hospital, a free-standing psychiatric facility in the state of Illinois, started implementation of Zero Suicide in 2016 with a focus on care transitions as a key priority. This included implementing a “bridge appointment” that ensures patients meet with a clinician as part of the discharge planning process. They found that as of mid-2018, 90% of all patients being discharged from inpatient treatment received a “bridge appointment.” In 2017 there was a 21% decrease in the 30-day readmission rate compared to the previous year [59].

AtlantiCare Health System started Zero Suicide implementation in 2015, driven by internal data indicating only 50% of individuals discharged from the inpatient psychiatric unit attended their first scheduled outpatient follow-up appointment. To address this, a new suicide prevention protocol consisting of a bundle of interventions was developed to improve patient engagement. Their Zero Suicide initiative results demonstrated that from April 2017 through March 2018 all patients discharged from inpatient psychiatric care who participated in the protocol were offered an outpatient follow-up appointment within 48 h, and 100% of those same patients attended that appointment. Only 9% of patients who completed the protocol were rehospitalized at the inpatient psychiatric unit, compared to 22% and 30% of patients who did not complete the full protocol or declined involvement in the protocol, respectively [49].

The Chickasaw Nation Department of Health and Family Services began Zero Suicide implementation in September 2016, first starting in the emergency department and soon after expanding to all clinical settings (outpatient clinic visits, dental visits, emergency department visits, and acute and intensive care unit admissions). The department saw a number of key outcomes:

- Before Zero Suicide implementation, patients received similar care regardless of their level of suicide risk, and as a result, on average, 120–150 suicidal patients were admitted for inpatient treatment per year.
- Between December 2016 and June 2018, implementation of standardized screening, suicide risk assessment, collaborative safety planning, and follow-up care practices led to, on average, 200 diversions from admission to inpatient treatment per year.
- Cost savings estimates indicate that each inpatient admission costs approximately \$1100, and that diverting patients from inpatient care has saved over \$200,000 per year [19].

UMass Memorial Health Care system (UMMHC) has been implementing the Zero Suicide model primarily in the emergency department in a stepped approach since 2016. UMMHC found that different clinical settings required tailored approaches, as well as alignment with accreditation standards. Building screening and intervention tools in the electronic health record (EHR) helped to increase awareness and guide clinical action. Training needed to be continuous and integrated into clinical workflow. Documented screening rates are now over 90% across all emergency departments, with about 4% of patients screening positive for suicide risk. High rates of documented screening are encouraging, but true fidelity to screening can only be ascertained by direct observation, patient feedback, and improved detection.

US states also creatively and swiftly paved the road to supporting the uptake and dissemination of Zero Suicide. To support the adoption of the Zero Suicide approach in Connecticut, the Connecticut Suicide Advisory Board – the single statewide coalition for suicide prevention, intervention, and response – and the Institute of Living/Hartford Healthcare began co-chairing a monthly Connecticut Zero Suicide Learning Community (CT ZSLC) in October 2015. The CT ZSLC is an open group for health and behavioral health care staff interested in the Zero Suicide approach and its promoted evidence-based practices. CT ZSLC participants are provided with state and national resources and technical assistance, workforce peer-to-peer support, access to training resources, and encouragement to adopt the approach within their systems and promote the aspirational goal and philosophy of Zero Suicide beyond their four walls to their communities, impacting suicide statewide. To date, there are 36 member organizations, of which 28 are health or behavioral health care systems, and those 28 systems involve 49 sites. Thirty-seven of the sites are adopting evidence-based practices promoted within the Zero Suicide approach, and 19 of them are adopting the Zero Suicide approach in its entirety (Andrea Duarte, Connecticut Suicide Advisory Board, personal communication, August 26, 2020).

The Zero Suicide efforts within Texas public mental health agencies in 2013 was strengthened by support for the development of Suicide Safer Care Communities, which were envisioned as communities implementing best practices in identifying and referring individuals at risk of suicide, reducing access to lethal means, coordinating care across health care providers, and providing best practice postvention support. Training was provided as well as coalition building, awareness building, and community planning. Regional suicide prevention summits were held to educate practitioners and disseminate strategies. As a result of their Zero Suicide activities, strong continuity of care was achieved, workforce confidence increased, and fewer cases were referred for hospitalization relying instead on the outpatient providers [41].

In 2012 in Kentucky, following the release of the Action Alliance report, Kentucky's Department for Behavioral Health, Development, and Intellectual Disabilities (DBHDID) decided to look at data as a first step in enhancing the ability of Kentucky's state psychiatric hospitals and community mental health centers (CMHCs) to prevent suicide. DBHDID and the state Office of Vital Statistics negotiated a memorandum of understanding to share data monthly between the departments. This allowed DBHDID to get a more accurate picture of the suicide deaths of CMHC and state psychiatric hospital patients in Kentucky.

Using the data from the Office of Vital Statistics, DBHDID identified suicide deaths among patients who had received mental health services from a CMHC or state psychiatric hospital in the year before their death. These clients were found by matching social security numbers between the two data sources. Cross walking the DBHDID data and the Vital Statistics data revealed that from 2007 to 2013, 24–30% of people who died by suicide in Kentucky in any given year had received services from the public behavioral health system in the 12 months before their death. Among state psychiatric hospital patients, most suicide deaths occurred more than 4 months after admission. Clients served by CMHCs died by suicide at a rate of 80 per 100,000, while clients with at least one state psychiatric hospital admission died by suicide at a rate of 340 per 100,000. (The national average during this same period was 12 per 100,000). This crosswalk looked at if and when patients receiving care by the state died by suicide was trailblazing at the time and others have since followed [75].

Zero Suicide has produced good results in early implementation around the globe. St. Joseph's Health Care London is a large academic health care organization serving London, Ontario, Canada, and the surrounding region. They began implementing Zero Suicide in 2016. After assessing for organizational readiness and staff experience with providing care for patients at risk for suicide, they developed a comprehensive training plan and instituted new protocols and workflows related to treating patients at risk for suicide. St. Joseph's observed several key improvements from 2016 to 2019:

- Increase in screening rates from 0% to over 90% for individuals in the Adult Ambulatory Mental Health Care program.
- Increase in completed suicide risk assessments from 48% to 100% for individuals in the Adult Ambulatory Mental Health Care program.
- Increase in comfort levels related to discussing suicide and the destigmatization of the word *suicide* among both clinicians and those receiving care (based upon qualitative data provided by focus groups) [3].

The Gold Coast Mental Health Specialist Service in Queensland Australia began Zero Suicide implementation in 2016. With a strong focus on building a restorative just and learning culture, within 2 years the service had achieved demonstrable and positive changes [61]:

- Decrease in suicide risk stratification (without care pathways/suicide-specific plans relevant to risk level) from 88% to 11% with a shift to a more dynamic approach to risk assessment.
- A large increase in the development (and quality) of safety plans for consumers from 1% to 52%.
- Increase in addressing lethal means from 11.4% to 68.4%.
- Increase in people receiving community follow-up within 2 weeks of being discharged from the emergency department. In 2015, 13.6% of people received follow-up; in March/April 2017, 46.3% of people received follow-up. In July 2019, 45 patients out of an eligible 47 patients identified as at risk for suicide were seen within the 2 weeks (95.7%), with 74% of people seen within 48 h.

The strategy, timeline, and pattern of Zero Suicide implementation varies among health care organizations, states, and countries. Clearly adopting and embedding the entire model with fidelity takes time and is not a linear process. But the array of early adopters favorably impacting care and outcomes suggests that suicide is no longer insurmountable in health care.

Implementation Resources

As previously mentioned, in the year following the release of the task force report, the SPRC, home to the Action Alliance, launched a free website (www.ZeroSuicide.com) to support Zero Suicide diffusion and uptake by describing the aspirational and ambitious goals of Zero Suicide along with providing an implementation toolkit and resources to reach these goals. The toolkit initially focused primarily on behavioral health but has since expanded to include information for specific settings and stakeholders – AI/AN, military/veterans, emergency departments, inpatient psychiatry, primary care, youth, substance misuse, health plans, states, and others, and it continues to evolve. In addition to multiple specific tools (described below) that health care systems should use to frame and launch their initiatives, the SPRC also moderates an active online e-community (Zero Suicide listserv) where participants engage in compelling conversations across diverse topics about best practices and share organizational resources. The Zero Suicide website includes a wealth of information that describes the framework and walks those responsible for this hard work through the steps to achieve their goals. Available on the Zero Suicide website are:

- **Organizational Self-Study:** In 2012, the Kentucky state suicide prevention coordinator, Jan Ulrich, thought about how to help health care administrators understand and launch Zero Suicide. She created a checklist for them to complete about their commitment, training, and inclusion of each of the seven elements into their system's care and used it as a tool to move leadership toward change. That became the prototype for what is now called the Zero Suicide Organizational Self-Study (available digitally and downloadable), developed by the SPRC as part of the online toolkit. The Organizational Self-Study serves as a needs assessment and is designed to assess what components of the comprehensive Zero Suicide approach are currently in place at a health care system and the degree to which the components are embedded within key clinical areas. The Organizational Self-Study also helps to assess organizational and clinical area-specific strengths and opportunities for development across each component. A five-point Likert scale anchors responses across each of the domains. Leadership teams from health care systems are strongly encouraged to take the Organization Self-Study early on in their launch and to take it annually thereafter to track progress. To date, almost 500 systems have taken the Organizational Self-Study. There is a version available specifically for inpatient psychiatric settings as well.
- **Outcomes:** The state of New York used the Organizational Self-Study to examine fidelity to the Zero Suicide model across its nonhospital public mental health clinics as part of a statewide implementation effort involving about 200 clinics.

They found that the scale has satisfactory psychometric properties (e.g., internal consistency). Additionally, the New York team assessed the validity of the scale by comparing ratings with histories of suicide incidents (generally, reported attempts). The analysis showed that for each point increase in fidelity (from 1–5 on the Organizational Self-Study), clinics were 69% less likely to have a suicide incident, validating the validity of the scale, and of the Zero Suicide model. The largest effect sizes were observed for organizational practice items related to clinic quality improvement infrastructure and lethal means reduction [39].

- **Workforce Survey:** Recognizing that one component of the Zero Suicide model is a competent, confident, and well-trained workforce, regardless of role or responsibility, the Zero Suicide Workforce Survey was developed. It can be used to assess staff self-perception of their knowledge and comfort interacting with patients who may be at risk for suicide, including comfort and skill providing specific elements of care such as screening, treatment, and support during care transitions. It can also assist the implementation team in designing and prioritizing training needs. Initially developed by Task Force Co-chair David Covington as an early contribution to quickly scale up Zero Suicide efforts, the SPRC adapted and expanded its use for a variety of settings, including corrections. The Workforce Survey is intended to be administered to the organization's entire workforce with branching logic for those not involved in direct care. The organization shares a unique link with their entire staff to complete the survey anonymously regarding their perceptions of their comfort, confidence, skill, and training in providing effective suicide care. Recommendations for administering the survey and interpreting results are found on the Zero Suicide website.
- **Outcomes:** Findings from the survey suggest that the clinical workforce does not feel knowledgeable about warning signs for suicide, know organizational procedures to follow when they suspect elevated risk, and are not confident about their ability to respond. Among those *responsible for delivering treatment*, fewer than half have received training on suicide-specific, evidence-based treatment approaches [9].
- **Data Elements Worksheet:** The Data Elements Worksheet is intended to assist health and behavioral health care organizations in developing a data-driven, quality improvement approach to suicide care. The worksheet 1) reflects the top areas of measurement that behavioral health care organizations should strive for to maintain fidelity to a comprehensive suicide care model, and 2) includes a list of supplemental measures that organizations may want to consider. A data dashboard is currently in development and will be available on the Zero Suicide website in 2022 for health care systems to enter and track their data.
- **Financing Worksheets:** Resources are available that provide guidance on how to optimize workflows and billing practices to better finance the delivery of improved suicide prevention services that align with the Zero Suicide model. These resources are designed to serve as tools that health and behavioral health care organizations can use to maximize reimbursements for suicide prevention services and summarize existing reimbursement mechanisms available for delivering components of suicide care.

Zero Suicide Training

As Zero Suicide began to emerge as a viable model, SAMHSA supported training to health care systems in the form of a Zero Suicide Academy designed and delivered by SPRC. Zero Suicide Academies were held in 2014 and 2015 to support early adopters who applied to attend. During these 2-day in-person events, teams of four people from each health care system gathered to learn from Zero Suicide implementers and suicide care experts, received implementation consultation, and began strategic planning for their own Zero Suicide initiative. Participants learned how to incorporate best and promising practices into their organizations and processes that work to improve care and safety for individuals at risk of suicide. These events were well-attended and well-regarded, and health care systems and states asked that they be delivered locally.

As a result, the Zero Suicide Institute (ZSI) at the Education Development Center (EDC) was established (www.ZeroSuicideInstitute.com). EDC is a global nonprofit with almost two decades of leadership in national suicide prevention in the USA. EDC has been home to the federally funded Suicide Prevention Resource Center (SPRC) and the Injury Control Research Center for Suicide Prevention (ICRC-S), and EDC provides secretarial leadership for the Action Alliance. Therefore, ZSI was the natural evolution to support the growing demand for implementation support, training, and consultation on the Zero Suicide model. The Zero Suicide website continues to be a free, publicly available resource for anyone interested in adopting Zero Suicide, while ZSI offers fee-for-service consultation and training both in person and virtually to health care systems, health plans, states, and others as they adopt, sustain, and evaluate their efforts.

Suicide Care As a Public Health Initiative Within Health Care

Addressing suicide prevention in health care settings should follow lessons learned from other top ten health care problems, which have been addressed successfully. Cardiovascular disease (CVD) is a useful comparison because it is the largest cause of death in the USA and because rates of death have declined in the same post-2000 period in which suicide rates increased [66]. Similar to CVD (and other illnesses), suicide interventions can take place over a continuum from “upstream” prevention efforts to interventions for people at elevated risk to intensive medical treatments. Figure 3 provides examples of this model for both CVD and suicide.

The suicide prevention field, anchored in a public health model, has emphasized upstream preventive strategies, including steps like promoting economic security (thereby reducing stressors that could ultimately lead to suicide), in its plans and proposals. But this strategy has not been effectively translated into action, and rising rates of suicide have persisted. Considering CVD efforts as an analogue illustrates why.

The most robust – and effective – upstream prevention effort to reduce CVD mortality has been smoking cessation. Work on reducing smoking has been *broad*

	Upstream Health Promotion	Preventive Interventions for Those with Risk	Treatment
CVD	Prevent Smoking	ID and Manage • Hi cholesterol—statins • Hi BP—ACE inhibitor, etc.	Interventional Cardiology • Stents • Valves
Suicide	Prevent or Resolve • Trauma • Depression • Addiction	ID and Manage Suicidality • Safety planning intervention • Reduce lethal means • Caring contacts	Treat Suicidality • Ct-SP • Dialectical behavior therapy

Fig. 3 Examples of prevention, intervention, and treatment options: CVD and suicide

(e.g., messaging via advertising and labeling about health risk on every package of cigarettes), *deep* (significant tax increases on the purchase of tobacco products have increased their price dramatically), and *long* (with the first Surgeon General’s report on smoking released in 1964, and a total of 29 reports issued by the Public Health Service since 1964) [56]. These efforts have led to significant reductions in smoking and reduced deaths from CVD [35]. One study showed that reduced smoking in Massachusetts contributed to a 31% reduction in CVD mortality during this period.

Upstream prevention activities to reduce suicide are arguably much more difficult to implement than reducing a single prominent cause of death like smoking. There are many “risk factors” for suicide, and many are only distally related to suicide. For example, economic insecurity causes stress than can eventually contribute to suicidal impulses; analyses have suggested that a \$1 increase in the minimum wage would yield a 2% reduction in suicide [22]. But such an increase is, politically, very difficult to achieve, and if put in place would yield only modest reductions in suicide. Risk factors for suicide that are comparable to smoking’s impact on CVD deaths include mental illness, substance misuse, and childhood trauma. But dramatically reducing these conditions or their impact would require unprecedented changes. And perhaps most importantly, investments in suicide prevention are miniscule compared to the scope of the problem; direct federal investments to date have been well under \$100 million per year, including dedicated efforts within the Veterans Administration of comparable scope. Reducing suicide via upstream prevention activities is very desirable, but realistically very difficult to achieve at a scale that will make a difference.

For both CVD deaths and suicide, intensive interventions are effective – stents to reduce arterial blockages in the case of coronary artery blockages and DBT for intense suicidality, respectively. However, these measures do not affect population-level death rates very much since comparably few people receive them. By comparison, targeted interventions for people with established risk of CVD (e.g., elevated cholesterol or blood pressure) are used widely. Screening for risk is ubiquitous, and prescribing a statin is easy. Ioannidis [31] estimated that as many as a billion people worldwide might be taking statins by 2020. While the allure of these drugs has receded somewhat, their spread illustrates the potential impact of targeted preventive treatments. How might suicide prevention compare?

The good news is that screening for suicidality is relatively simple and can effectively focus attention on individuals with elevated risk. Also, evidence has begun to emerge on the effectiveness of simple interventions (e.g., safety planning, removing or reducing access to lethal means, “caring contacts” to people at risk). These interventions are all very feasible in ordinary health care settings; a single safety planning intervention can be conducted in 30–45 min and letters or texts can be sent as caring contacts. The challenge, however, is to change the culture of health care settings – first to make concern for suicide a central task so that screening for suicide risk is as ubiquitous as blood pressure checks for CVD risk, and second to “install” the effective brief interventions as routine parts of care.

Creating a Movement

The developers of Zero Suicide were clear that achieving widespread adoption of Zero Suicide would be challenging. Macchiavelli’s admonition about the difficulty of introducing “a new order of things” still rings true: “There is nothing more difficult to take in hand, more perilous to conduct, or more uncertain in its success, than to take the lead in the introduction of a new order of things. Because the innovator has for enemies all those who have done well under the old conditions, and lukewarm defenders in those who may do well under the new” [45].

The challenges would be significant because suicide prevention was not an established priority for health care settings (except for a requirement by the Joint Commission [34] treating suicides of patients *within the hospital* as a “sentinel event”). Also, health professionals were not trained in detecting and managing suicidality, the outcome of suicide was not measured for health care settings, and financing was not provided. Recall that the initial National Strategy for Suicide Prevention did not include a goal on suicide prevention in health care settings; this goal was added to the revised strategy in 2012. This would be an uphill slog.

Several strategies used in promoting evidence-based mental health practices were built into the early Zero Suicide dissemination and adoption effort. In addition to the online toolkit, scores of presentations promoting Zero Suicide were given at state and national conferences and meetings, especially for mental health organizations and suicide prevention advocates where adoption would be somewhat more familiar. The leaders and spokespeople for the national Zero Suicide movement were primarily the task force co-leads, SPRC leadership, and a handful of early adopters (this list includes the authors of this chapter). They were a small, well-organized, well-connected group, doggedly committed to seeing Zero Suicide installed in health care.

Crucial support for adoption and spread came from SAMHSA, which provides only modest ongoing funding for mental health and addiction care but has active grant-making programs to support change in areas such as suicide prevention. At the time of the launch of Zero Suicide, the only significant grant program in suicide prevention was supported by the Garrett Lee Smith Memorial Act, signed into law in 2004. Soon after the initial development of Zero Suicide, SAMHSA leadership

emphasized Zero Suicide activities as one desired element of youth suicide prevention. Enacted in December 2016, the twenty-first Century Cures Act authorized grants for adult suicide prevention for the first time, and SAMHSA made implementing Zero Suicide a primary requirement of these grants. The funding and imprimatur provided by SAMHSA was a critical motivator for dissemination of the approach. The National Institute of Mental Health (NIMH) began offering Zero Suicide grants in 2016 and Indian Health Service (IHS) offered grants in 2017.

Increasing expectations for suicide prevention were established by accrediting bodies, reflecting initial steps to establish suicide prevention as a core responsibility of accredited providers (Goldstein Grumet [25]). The Council on Accreditation, which accredits counseling practices, upgraded its standards for screening, assessment, and management of suicide in 2018 [17]. The Joint Commission, the major accreditor of hospitals, signaled a greater focus on suicide prevention with a non-binding but comprehensive advisory in 2016, and then in 2019 established suicide prevention for all individuals under care for a behavioral health condition as an accreditation standard for accredited hospitals and behavioral health organizations [33]. In 2020, the Joint Commission made these standards applicable to small critical access hospitals (Goldstein [25]). In 2016, CARF International, published a Quality Practice Notice on Suicide [15], followed by incremental steps toward stronger suicide prevention practices, resulting in a 2019 assessment standard requiring programs accredited under CARF's Behavioral Health and Opioid Treatment Program Standards to conduct suicide risk screening for all persons served ages 12 and older. Just a decade ago, suicide prevention in health systems was an unsystematic effort largely emphasizing "containment" of suicidal people in psychiatric units and a modest priority for an underpowered suicide prevention field that was largely focused on an unrealistic upstream prevention agenda. By 2020, preventing suicide has become an explicit expectation for all accredited mental health providers and hospitals and a major priority for a suicide prevention field that is re-energized. But at the same time, overall rates of suicide have risen and large segments of the health care system (e.g., most primary care practices, most health plans) are not committed to the aspirational goal of eliminating suicide among people under care. There is still more to do.

An International Declaration

In 2014, nearly 30 advocates from eight countries convened in Oxford, United Kingdom, for a 2-day suicide prevention planning group as part of the International Initiative for Mental Health Leadership (IIMHL) conference and exchange. About 15 of these individuals were pioneers pursuing the Zero Suicide model within their respective countries, most notably New Zealand, the Netherlands, the United Kingdom, and the USA. Zero Suicide International summits were held subsequently in Atlanta (2015), Sydney (2017), and the Netherlands (2018). In 2019, the Rotterdam International Declaration was published, representing the work of over 100 innovators from nearly 20 countries.

Dutch psychiatrist Jan Mokkenstorm was a critical international leader in the movement, declaring in 2014 that Zero Suicide was about the bold goal that “no one die alone and in despair.” In 2017, he published “Is It Rational to Pursue Zero Suicides Among Patients in Health Care?” in *Suicide & Life-Threatening Behavior* [48]. Also in 2017, in the United Kingdom, MerseyCare NHS Foundation Trust Chief Executive Joe Rafferty was named in the Health Service Journal’s list of the top 100 most influential people in health. During that same year, in partnership with Steve Mallen, chair of the MindEd Trust, Mr. Rafferty launched the Zero Suicide Alliance, which includes 90 NHS trusts, charities, politicians, and suicide survivors. The groundbreaking alliance was announced at the Houses of Parliament and included government funding and an online training course called Save A Life.

In 2016, Kathryn Turner and the team at Gold Coast Health published a new suicide prevention strategy with a bold incorporation of the Zero Suicide model. By 2018, 11 of the 16 health regions in Queensland were following suit. Creating a “just culture” that is restorative and focused on looking forward to learn, heal, and improve is central in the Gold Coast philosophy, building off the work of Sidney Dekker’s safety culture. Supporting staff with three tiers of resources and responses also differentiates this Australian adaptation, with professional referrals, “always there” team responders to offer psychological first aid, and formal and informal supports. The Gold Coast success has been the catalyst for the uptake of the Zero Suicide model in New South Wales, the largest state in Australia. In 2018, the state government announced an investment of almost \$90 million to reduce suicides by 20% by 2023. Part of that investment is \$10.2 million to reduce suicides and attempted suicides within health services across the state using the Zero Suicide model as the foundation for systems change.

In 2017, Ian Dawe, program chief and medical director for mental health at Trillium Health Partners in Ontario, Canada, led the publication of *Strengthening Suicide Prevention in Ontario Hospitals*, which had as its top recommendation implementing the Zero Suicide model in hospitals across the province. Today, Ontario’s Project Zero is rolling out the hospital initiative and adding components of population health, targeted clinical training for community mental health (DBT, etc.), and investment in training for schools, including mindfulness. In 2018, they received \$three million in government seed money. Their team believes the interest and engagement is going to yield a significant investment, as these top leaders have led the charge and expanded it to a vision of eliminating suicide among children and youth by 2027.

Zero Suicide continues to expand globally, incorporating adaptations that are necessary and relevant to local needs and norms but nonetheless maintain at their core that suicide is preventable and that people have the right to access care that is supportive.

Integrating Lived Experience Into System Design

A 2020 Harris poll revealed the barriers that continue to exist preventing people who are thinking about suicide from seeking help: feeling like nothing will help (67%), lack of hope (63%), not knowing how to get help (55%), and embarrassment (55%) [2].

It is worth noting that this reflects a downturn from 2018 where 63% of respondents quoted embarrassment as a barrier. While the overall population is growing slightly more comfortable with talking openly about suicide, rates of suicide continue to rise, and the poll findings suggest that the lack of trust the American people have that the health care system can do anything to make them feel better is a factor. It is also extremely common that law enforcement is the first responder for individuals who reach out for help or raise concerns for others. The Treatment Advocacy Center's *Road Runners* report (2019) [76] states that 10% of law enforcement budgets is dedicated to engaging and transporting people in a mental health crisis. These barriers to immediate care that is compassionate, effective, and standardized make the work of Zero Suicide much more difficult.

Henry Ford Health System's Perfect Depression Care initiative was the result of an Institute for Healthcare Improvement grant and personal interactions with the review committee led by Dr. Donald Berwick. In 2009, Dr. Berwick wrote, "What 'Patient-Centered' Should Mean: Confessions of an Extremist," in which he described a paradigm shift in health care: "Proper incorporation [of patient centered care] into new health care designs will involve some radical, unfamiliar, and disruptive shifts in control and power, out of the hands of those who give care and into the hands of those who receive it" ([4], p.w555). Personal conversations with Dr. Berwick offer that he sees no differences in the efforts to provider safer suicide care and tackle other complex challenges, like hospital-acquired infections. Performance improvement must include a sea change in the inclusion of people who lived with the medical condition, in this case individuals who have lived with suicidality and/or survived a suicide attempt.

In 2014, the Suicide Attempt Survivors Task Force of the Action Alliance (2014) published *The Way Forward: Pathways to hope, recovery, and wellness with insights from lived experience* [53]. Later the same year, a summit on integrating the efforts of the Zero Suicide and lived experience task forces was convened in California by the Mental Health Association of San Francisco. Suffering and courage were major themes and were described as essential elements that unite and strengthen the work. Dr. Berwick's landmark article suggests shifting these efforts from token representation to "radical" inclusion may turn the tide and shift America's heart and soul on the challenge of suicide.

Future Directions: From Grants Supporting a Mental Health Initiative to Installing Suicide Care As a Core Activity of Health Systems

To date, Zero Suicide has effectively pursued an "early adopter" approach to making suicide a core priority in health care. As of 2021, there are well over 2000 health care systems in the USA "doing" Zero Suicide and more across the globe, but this self-report perspective does not provide much knowledge about the quality of implementation or the results achieved. When asked, many of these systems will describe their Zero Suicide efforts as enhanced screening protocols or the standard application

of caring contacts. These steps represent a significant improvement of practice but are not the same thing as implementing the full bundle of interventions that achieved significant results at HFHS or Centerstone. Fidelity and commitment to the seven components that make up the Zero Suicide model need to be relentlessly adhered to but are challenging to maintain. Suicide care within the current health care constellation is complex and our learning about how to identify and care for those at risk is not linear. One implementer in Australia describes this as “‘inconvenient truths’ that must be identified, reconciled and integrated into our future pathways towards reducing suicides in health care” [77].

The results of Zero Suicide implementation over the past decade present several paradoxes. On the one hand, adoption has moved more swiftly than the uptake of many other research-backed, “evidence-based programs” in mental health, such as supported employment [21] or multisystemic therapy. In the case of these and other effective practices, estimates are that only 2–10% of people who could benefit from them actually get research-proven interventions [29, 65]. Because of the combined effect of SAMHSA leadership and grants, encouragement by SPRC and suicide prevention advocates, and recent changes by accrediting bodies, improved suicide care has spread more broadly. But the precise degree of spread and fidelity of implementation are uncertain.

This challenge leads to bigger opportunities and challenges if effective suicide care is to contribute to a lowering of death rates. The opportunity is bigger because of concerns due to rising rates and because the multiple stresses associated with the global COVID-19 pandemic have led to an increased focus on mental health and suicide prevention – illustrated by the Federal Communication Commission’s designation of 988 as a single national telephone number for suicide prevention and mental health crises. The opportunity is also amplified because of recognition and concern that economic and social forces have contributed to the “diseases of despair” that have now resulted in a reduced life expectancy in the USA 4 years in a row.

The challenge is larger because making good suicide care available broadly enough to affect overall death rates requires changing practices and priorities in settings where the need for change is not yet widely recognized but where the majority of patients with suicidality are seen (e.g., primary care and emergency departments). The feasibility of providing necessary suicide care in these settings is often perceived as low, given time constraints and the often-inadequate availability of mental health personnel.

To speed up adoption in these and other settings, and using the available evidence that now exists, quality measures should be created that focus on suicide care. Payers should create value-based care payment bundles that build the critical foundations for the effective and sustainable delivery of suicide care in health systems.

Health plans and payers offer leverage to ensure that physicians use suicide care best practices, but payers need guidance and leadership in this space. As a result, in 2018, the Action Alliance (2018) released *Recommended Standard Care for People with Suicide Risk: Making Health Care Suicide Safe* [52]. The report presents specific recommendations for four settings: primary care, outpatient behavioral health care (mental and/or substance use treatment), emergency department, and

inpatient behavioral health care (hospital-level psychiatric or addiction treatment). These recommendations present feasible, practical, evidence-based actions that health care organizations can adopt immediately, actions which are drawn from the Zero Suicide model but do not equate to taking on the model in its entirety.

Genuine culture change is critical to truly impact suicide care, and that includes within higher education as well. The lack of training, and therefore competence, in the clinical workforce continues to impact how people at risk for suicide are treated both because the evidence-based practices that exist are underutilized, as well as because workforce anxiety and predilection toward seeing suicide as something that is not preventable impacts patient outcomes and engagement. Robust, current, and ongoing suicide care best practices need to be integrated into the full breadth of allied health professional graduate and residency training from social work to medicine to family practice. This needs to include an emphasis on specific safe and effective suicide care practices (screening, assessment, safety plans, caring contacts, etc.) but also on understanding restorative just culture in the context of suicide care. A handful of medical schools have chosen to embrace teaching suicide-specific strategies and the applicability of six sigma principles, but these are few and far between, with most medical students getting no more than a class or two in suicide care before launching their careers.

There must be a continued investment in research focused on brief, cost effective interventions and how to better engage people at risk for suicide, as well as on who should deliver these interventions. For people considering suicide, health care should be a sanctuary where providers and all staff make patients feel comfortable and cared for and offer reassurance that care works and their life matters.

Finally, pursuing continuous quality improvement and accurate data collection is challenging and necessary for Zero Suicide implementation, but more importantly it is essential for improving the care delivered to people at risk for suicide. There is evidence for each of the seven elements of Zero Suicide and the results thus far suggest that full-scale implementation of this model is feasible and effective. Many health care systems, once they are past the hurdle of adoption, begin grappling with how best to analyze and report on the impact of their Zero Suicide initiatives. Definitions of events and the metrics used to assess outcome can vary by organization. Continued research to refine and improve evaluation of the Zero Suicide model is necessary.

Conclusion

When implemented with fidelity, Zero Suicide is an effective approach to “suicide care” that has dramatically reduced death rates in health care organizations. The model has been widely promoted, but the full scale and integrity of implementation is uncertain. Additionally, aspects of the model, such as screening and the use of brief interventions, have also been shown to be effective and are being implemented widely with encouragement from accrediting bodies. However, this broad but uneven implementation is centered in behavioral health services and is just

beginning to see use in hospitals. The reluctance to integrate mental health care into medical settings, though still present, is beginning to wane. While there is still more to master, competence is now expected by accreditors, and movement toward this is apparent.

Evidence on the feasibility of screening for suicidality and the effectiveness of brief interventions offers the promise of changing the trajectory of suicide in primary care the way that screening for CVD (blood pressure, lipid levels) and preventive interventions (statins, diuretics) have changed CVD death rates. Primary care settings are expected to monitor CVD conditions and indeed to manage most CVD care, with cardiologists available to handle more complex care. Getting screened for CVD at every visit is routine and expected without regard to cost, stigma, or time constraints. Likewise, standard suicide prevention screening and interventions must be just as integral a part of care as we have come to expect for other medical conditions. But this “change challenge” remains difficult to overcome.

Organizations that have adopted Zero Suicide have demonstrated that the use of this bundle of practices improves care and saves lives. The Zero Suicide model represents a commitment to patient safety – the most fundamental responsibility of health care, to the families and friends of those at risk who want to know that their loved ones are safe and properly cared for, and to the safety and support of health care staff, who do the demanding work of treating and supporting suicidal patients.

Abstract

Is suicide really preventable? What is our role in suicide prevention and do we really even know what that looks like? As deaths by suicide continue to occur year after year and country by country, it is time the field of suicidology changes course. Despite financial investments in the study and understanding of suicide, treatments and interventions, awareness and education campaigns, and countless programs having been developed, none have provided us a way to significantly reduce the burden of suicide in the world on a sustained basis. It is for these reasons we must all individually and collectively look inward as we change the direction of suicide prevention.

Self-Disclosure: Part 1

I struggled to write this chapter. I have so many questions, but more frustration. I wondered to myself for so long if I should even proceed with the chapter. I spent countless hours asking myself how this chapter would make any sense in a book on “Suicide Risk Assessment and Prevention” including chapters written by highly reputable and notable colleagues from around the world. I wondered if I could find a way to justify that this chapter would fit into this compendium of scientifically and/or theoretically based chapters when it would not at all be about science, research or theory. Then, just days before sitting down to type out my thoughts, I was scrolling through television stations and happened to come across a physician on a news program in the USA. The interview was about the Covid-19 pandemic and the more than 200,000 lives lost in the USA as of September, 2020. I did not catch his name, but a statement he made captured my attention: “It is really hard to tell families that have lost someone that their death might have been preventable.” It was a moment that led me to decide I could write this chapter in the hope that somehow for any who chooses to read it among the far more brilliantly written chapters in this book, they too will come to the conclusion that I have: something is wrong with our approach to suicide prevention.

Is Suicide Preventable?

Recently I was asked to conduct a Grand Rounds training for a large medical center and the audience was 80% physicians and 20% nurses, notably 0% from mental health. I was specifically asked to address the audience and answer the question: if we can’t predict suicide with any accuracy, why are we trying to in the first place? In my presentation I used every spin that I could to say, “We can’t prevent every heart attack or stroke, but we still try.” My message to them, and here, is that on some level we must hold onto the belief that suicide can be prevented and that somehow we can have an impact on it being prevented. Yet, it may be time for our field to accept that not every suicide can be prevented and we may want to start finding a way to acknowledge this while still providing hope that for many we can. If we do not begin to look at this, the conversations that we have with suicide loss survivors will continue to be filled with justifications, excuses, and explanations that fall short of what reality is.

Everyone is going to die of something, but does suicide have to be on that list? If it is in fact true that suicide is a preventable death, why does the prevention of it remain so elusive to us? Is it not fair to ask ourselves if we just need to accept that there will be X number of suicides in the world each year? If we can agree on this we would at least have a baseline upon which we could assess our work at preventing suicides. In a year where we would be below the “accepted” number of suicide deaths, we “celebrate” our victory, although personally if we have one death that same year I propose we not celebrate at all. Conversely, in a year where there are more than our “accepted” number of deaths who should be held

accountable and how? If there is only one more death should it be more acceptable than if there were 1000 more deaths? How does the Zero Suicide movement factor into this? Is it just an aspirational goal or a real possibility and if it is real what has kept it from happening – anywhere? I suggest that none of this is possible, realistic, or in our near future. We are nearing the end of 2020 and to-date there has been no sustained, successful models of suicide prevention that have been implemented anywhere at scale, demonstrating a significant, long-term reductions in the burden of suicide. Further, if there were such a program, what has kept it from being the foremost effort for the rest of the world in being replicated? Regardless of fluctuations in suicide rates each year and around the world, how is this possible that we haven't made the progress in prevention of suicide that so many of us have been searching for over?

What brought you to the field and study of suicide may have been an interest in the brain or the environment. It could have been an interest in psychology and human behavior. It might have resulted from a personal experience of your own facing the darkness of death by suicide or the loss of a loved one in your life. Something drew you to this work and keeps you here. All of the many possible reasons that you came to this field might also be the things that keep you engaged in it as well and, in part, that is because we are not there yet. Despite all of our advances and understanding, the reality is that I do not know one person that can assuredly tell me that they can prevent all suicides. In fact, among virtually all that I know, the closest and most frequent thing that I hear is that “we believe we can prevent suicide” and “if we use evidence-based treatment we can prevent suicides.” I also frequently hear from colleagues “we can't prevent all suicides, but most.” And yet, most of us tell people all of the time that we can prevent suicide. Just look at a few publicly available statements to this effect:

- Suicide is a serious public health problem; however, *suicides are preventable* with timely, evidence-based, and often low-cost interventions. (<https://www.who.int/news-room/fact-sheets/detail/suicide>. (Retrieved Sept. 26, 2020, emphasis added).
- Suicide is a major public health concern. Suicide is complicated and tragic, but *it is often preventable*. Knowing the warning signs for suicide and how to get help can help save lives. (<https://www.nimh.nih.gov/health/topics/suicide-prevention/index.shtml#:~:text=Suicide%20is%20a%20major%20public,help%20can%20help%20save%20lives>. (Retrieved Sept. 26, 2020, emphasis added).
- *Suicide is preventable*. Knowing the risk factors and recognizing the warning signs for suicide can help prevent suicide. (<https://www.psychiatry.org/patients-families/suicide-prevention>. (Retrieved Sept. 26, 2020, emphasis added).
- “The foundational belief of Zero Suicide is that *suicide deaths* for individuals under care within health and behavioral health systems *are preventable*.” Suicide Prevention Resource Center, USA. (<https://www.sprc.org/zero-suicide>). (Retrieved Sept 26, 2020, emphasis added).
- “*Suicide, a preventable cause of death*.” Aviva Parvez Damania, The Indian Express, June 15, 2020. (Retrieved Sept. 26, 2020 from: <https://indianexpress>.

[com/article/lifestyle/health/suicide-causes-signs-prevention-awareness-counseling-6460322](https://doi.org/10.1007/978-1-4939-9646-0_322), emphasis added).

I have also said to myself and often hear colleagues claim: “It is impossible to measure prevention, so we don’t know how many lives we have saved (prevented) from suicide.” We say it publicly, in writing, in training and we hold onto the belief that we can prevent suicide, yet, tragically and with all humility on the line, in my opinion the reality is that we are failing. We are failing the estimated 800,000 who die each year to suicide. We are failing their families, their communities, and ourselves. It is because of this I believe now is the time we must turn inward to move forward; but first a note on the challenge of risk factors.

Is There Any Value in Suicide Risk Factors

Despite highly reputable evidence to the contrary (see below), our field continues to rely on assessment and use of risk factors as part of our attempt at suicide prediction. While true most clinician and research studies on the topic will suggest it is only a part of a more comprehensive approach to suicide prevention, I have to wonder if it should be at all. Yet, our continued reliance on suicide risk assessment is incorporated into the title of this book!

Case Example 1 Maria is a 17-year-old, female that has been dating her boyfriend for just over 1 year. She is an A to A/B student in high school where she is involved in several extracurricular activities, including having a leading role in an upcoming school musical. Maria has no history of mental illness or substance use, she has no known history of family mental illness or substance use. Maria’s parents were high school sweethearts and have been married for almost 30 years. She has one brother that is 2 years younger than she is. Maria has a strong Christian faith, is actively involved in her faith community and a peer youth leader at her church. Maria has plans to go to college and study biology and theater.

Case Example 2 Nate is a 26-year-old single male. He has never been married and is intermittently involved in a relationship with the mother of his daughter. They recently learned she is pregnant with their second child. Nate does not live with the mother or his daughter. Nate did not finish high school. He is currently working for a medical technology company grinding wires that are used in brain surgery. Nate has a long history of mental health and substance use problems. He was diagnosed with ADHD and oppositional defiant disorder as a child. He was diagnosed with depression and intermittent explosive disorder in his early 20s and he has been using alcohol and drugs since he was 12. Nate also has a significant family history of mental illness and substance use including his mother who has been depressed for many years and both drinks alcohol to intoxication weekly and abuses prescription drugs. Nate’s dad recently passed away following an overdose of methamphetamine. His parents divorced when he was 10 years of age and he has two younger siblings

both with mental and chemical health problems. Nate has a long history of legal problems including a recent second DWI and a recent arrest for possession of methamphetamine.

Do you think that either Maria or Nate have no risk, low risk, moderate risk, high risk, or imminent risk? Given this book is about suicide risk assessment, I feel confident in assuming that 99% of those reading this chapter will assess Nate as being at least moderate risk and more likely at high risk, while also assuming Maria would be assessed to have no or low risk. Why is this? As stated earlier, despite research telling us to do otherwise, as a field we look at risk factors as both a contributing factor in assessment as well as an indicator of level of risk (i.e., the more risk factors the more risk). Here are just a few of the more recent and prominent examples of studies on risk factors.

Large et al. [1] from Australia conducted a meta-analysis of longitudinal cohort studies of suicide risk assessment of psychiatric patients who had made multiple suicide attempts reviewed in 37 published studies. They found that 95% of high-risk patients will *not* die by suicide at all and that 50% of patient suicides came from the lower risk categories concluding: “The strength of suicide risk categorizations based on the presence of multiple risk factors does not greatly exceed the association between individual suicide risk factors and suicide. A statistically strong and reliable method to usefully distinguish patients with a high-risk of suicide remains elusive.”

In the highly reputable journal, “The British Journal of Psychiatry,” Chan et al. [2] looked at predicting suicide following self-harm, an often claimed increased risk factor for suicide. In a meta-analysis of 12 studies on risk factors and 7 studies on risk scales, 4 risk factors emerged. They concluded: “The four risk factors that emerged, although of interest, are unlikely to be of much practical use because they are comparatively common in clinical populations. No scales have sufficient evidence to support their use. The use of these scales, or an overreliance on the identification of risk factors in clinical practice, may provide false reassurance and is, therefore, potentially dangerous.”

Finally, the Franklin et al. [3] study on risk factors provided a glaring view of this major problem in our field. In this study, a meta-analysis of 50 years of research on risk factors for suicidal thoughts and behaviors that has been cited over 1000 times, the authors found “Across odds ratio, hazard ratio, and diagnostic accuracy analyses, prediction was only slightly better than chance for all outcomes” and that “the predictive ability has not improved across 50 years of research (p. 1).” With all of the progress that we have made, our ability to prevent suicide is still no better than chance and it has not improved in a half century. It should, therefore, not be a surprise that both of these cases are real and today Nate is doing very well while Maria died by suicide 1 h after receiving a call from her boyfriend that he was ending their relationship.

The authors cited above looked at the work of many contributing authors to this field and seen throughout this book and shared the less than positive results. Publishing these results took courage. They made some bold statements, especially when so much of the field looks for suicide risk factors as a means of identifying those most likely at risk of dying by suicide. I have often wondered what it was like

for these authors when they first saw the results of the study and more, what would they write about it? I applaud them for their bravery and, while I have not asked any of them, I would suspect that one if not more of them had some thought and belief, but definitely some hope, that their study and statements would change our field. Yet, to-date, 4 years after the publication of their work, millions of lives have been lost, countless more have come close in attempts, innumerable numbers more have thought about suicide, and we still look at the long list of risk factors as somehow helpful in our assessment of who might die by suicide. If there is a nearly universal belief that suicide is preventable, why does the world continue to see so many deaths by suicide each year? These authors faced themselves in the mirror and we all need to do the same.

Turning Inward: Because We Have To

Not unlike many of you, I have been frustrated by our lack of progress in suicide prevention. I think that we must do something different, and soon, or we will continue to see the same problem for years to come: there will be more and more deaths by suicide. In fact, I would posit that if we do not stop, take a step backward and reflect, it will be difficult for us to see a different future, one in which suicide prevention is not just a noble career and life choice, but rather a reality that keeps people from dying at their own hands. For this to happen we will need to BOTH individually and collectively step away from our work and current beliefs about suicide and suicide prevention. It will require us to be introspective, not unlike what we ask of patients in psychotherapy. For the field of the study of suicide, much needs to be done but it must begin by looking in the mirror. By looking at ourselves and what we are doing, we can begin to figure out what it is that must change for there to be a different outcome.

I had the unfortunate but not unique moment to be sitting with an oncologist who gave us the news that it was stage 4 cancer with a life expectancy of 6 months to 3 years, most likely 15 months. Sadly and tragically for me and my family, he was right in his prediction – to the day. It was literally 15 months, *to the day*, from when we first met that he told us the news. Was it luck or has oncology come that far is not my point here. He knew what the outcome was going to be. He accepted it and while he did all that he could to provide comfort and care in those 15 months, the bottom line is that oncologists work against the clock of life accepting at all times that the disease is going to prevail. While true that something else might happen in the intervening months or years for some patients (e.g., car accident, stroke), at some point the disease will result in the person's death. Try as they do to prevent this and delay it, reality is also at play and oncologists live this every moment of their days. In several conversations with this oncologist it became clear to me that their field has come so much further than our field. Yes this is because literally billions of dollars more are funneled into cancer research, prevention, and treatment, but that is not what I am thinking about here. Rather, they have found ways to both communicate externally about the realities of the disease and death, while also internally accepting

the hard truth that they cannot prevent all of their patients from dying. I would argue that, after many of these conversations, it is clear to me that oncologists have looked in the mirror to be able to keep doing their jobs.

Should we too as suicidologists? Can we honestly be engaged in suicide prevention if we accept that not all suicides are going to be preventable? What should we tell families, friends, coworkers, and others about suicide prevention, or to families who have just lost someone to suicide? Do we tell them that suicide is preventable? I guarantee you they will see that online and they will hear it in the days ahead for them as they grieve not anything unlike the publicly available statements earlier in this chapter. How do we explain that “most suicides are preventable” but their loved one’s was not? If we chose not to say that suicide is preventable, how do we educate the public, no less other professionals, that suicide is preventable? Again, this is why we need to turn inward for direction.

What Does It Mean to Turn Inward for Direction?

It means admitting we do not have the answers, nor are as far as we would like to be. It means that we have to accept responsibility for our part of getting us to this moment, the good and the bad of that. It means accepting that our passion and even our expertise, whatever that may be, is not working. Turning inward means we have to be willing to tell ourselves that for whatever reason(s), no matter what our contribution to the field and the world we have had, be it large or small, long or recent, the goal remains clear but the path to achieving the goal elusive.

Turning inward means we stop and take the time to reflect on what other fields of study have done, accomplished, and overcome. That we try to discern if and what might apply to us in the study of suicide and prevention. It means we accept what makes this field different, and similar, to others. After all, our brain and our body are connected regardless of the disease or externally/environmental impacts, so it behooves us to try and learn from what other diseases have learned. What about “but there is no time to look inward, we have to keep moving forward.” I understand that belief and have battled with it myself. “If this program does not work, we will create another one.” The problem with this thinking is that we tend to not look at what did not work and why, but rather we continue to try new things. That would be fine if something worked, but let’s say we were trying to bring more light into a room so we decide to paint a wall and we thought using a brush would be best. We start and realize it is a lot of work and taking us too long, so we transition to using a roller. Now we have saved some time, but we are still doing the same thing. This seems good until we realize that we have only changed the applicator, the result is still we are painting. In our effort to speed up the process we move to a sprayer to get the job done more quickly. Highly efficient, same outcome. This all results in our wall being painted and upon completion of it in our pride and sense of accomplishment, we suddenly realize that it wasn’t really painting that the wall needed, but rather it was that the wall needed to come down for us to see that no matter what color or how bright it was that we painted the wall, without taking the wall down we were still

inside a room with four walls. To let the sunlight in we would need to open the wall. Ultimately, we needed to take a step back before we could move forward to see the light.

Self-Disclosure Part 2: Looking in the Mirror What I Saw?

It is hard to look at yourself. Each time you do you hope to see things the way you expect them to be, even the way you want them to be. You watch how things change over time. You learn how to ignore things that you can't do anything about and you accept that what you can change may not be quick or easy. Looking in the mirror is a first step toward seeing what we need to. As I did this, I saw things that I did not like.

A lack of answers. A lack of understanding. A lack of a real plan or strategy. Waste. Hundreds of millions of dollars in waste. A travesty in misleading the public, failure in training, and lost time. I see competition that is getting worse, not better nor moving us to more lives saved. I see a 180 degree swing from careful caution about the use of those with lived experience in research, awareness, education, etc., to full-on, complete, and driving-the-field-force by the lived experience voice. We support and stand behind someone with lived experience that creates a movement (e.g., Amy Bleuel) only to have her die by the same movement she has tried to stop, and yet we continue to endorse her vision of a semicolon as a symbol of hope. I see the wheel being recreated only using a different name. I see an entire field that lacks a definition (who is a suicidologist, how do you become one, what standards or ethics must you adhere to in order to be one).

I also saw my role in this that did not make me happy. I have continued to raise funds to create programs that have not turned the tide on suicide. I have talked with countless families and had to apologize for not knowing why their loved one died. I have spoken to and trained thousands of people to look for risk factors, warning signs that are all based on a 12-month span of time rather than a week prior to a death, how media influences contagion, and that evidence-based treatment exists for suicide prevention all the time knowing one painful fact: they are still dying. I have heard many people say that I saved their life or that of a loved one, while at the same time seeing even more people say that after hearing someone who attempted suicide and survived tell their story it saved their lives. Countless times over I have seen, heard, and read people say that they are alive today because of hearing a story from someone with no education, training, or expertise in suicide prevention or mental health. How can this be and if all it takes is someone with lived experience to tell their story, what are all of us doing?

The angst that I felt as I looked at my role in this was palpable and left me wondering if I was in the right career. Do I run and if so in what direction should I go? Can I be honest about this with my colleagues, after all many are disclosing their histories of challenges and we are supporting others in coming forward with their stories, but would this be okay to bring to light? Admitting and accepting what I saw was hard. I feared disclosing this to anyone and I questioned my more than 20 years of work in suicide prevention and 30 years in mental health. However, I knew that if

I could accept there has to be things unknown before they are known much less understood AND that I possibly could have a small piece in others looking at their role in this, maybe collectively we could all get to the next place, that place we need to be to save more lives.

What Is This Going to Do for me?

I have never been one much for using quotes of others, but this one seemed to fit too well not to use here: “Success is not final, failure is not fatal: it is the courage to continue that counts.” Winston S. Churchill.

After countless hours of looking inward, even around if I had the courage to write this chapter, I have decided to continue. I have decided that there is much for me and for this field to hope for, because I believe it can be different. By taking different steps in my work, I have hope that it will have a positive impact on others. Not unlike those with lived experience that we have heard tell us to support all those with sharing their voice because it will help us do our work better, I too hope that sharing this will encourage others to stop and reflect on what we are doing as a field and what we are doing individually. In a Crisis Editorial (Reidenberg, 2018 [4]) that I wrote: “I worry that in our field, SILOS are often Self-Interests that Limit Outcomes. It would be beneficial if we could take a new strategy and collectively focus all of our efforts around thinking, acting, and being CLEAR – Coordinated, Long-term, Effective, Accountable, and Resourced – in our approach to suicide prevention. The next time you want to try a new approach, ask yourself, “Am I in a SILO or am I CLEAR to proceed?”

I also hope that we can find new ways to see suicide prevention outside of risk factors and the challenges with suicide risk assessment. None of us can accurately predict who will die by suicide and who will not. We know that if we put two of us in a room with someone we will likely come out of it with vastly different views as to that person’s risk, if any. Thus, we might need to move away from a strong focus on trying to conduct suicide risk assessments – no matter how comprehensive – and accept we just can’t know if they will die or not, especially based on what or how many risk factors might be present. Instead, we might want to focus on trying to help them to live and how they can go about living as well as possible in whatever time that they have left, be it days, months, or years. I fully and wholeheartedly believe that when people are doing well in life, they are not dying by suicide. Maybe we should refocus our efforts in that direction, helping them to find purpose, meaning, and well-being. The oncologist said to us that when someone has cancer we want them to live their life just as they want to. They should do whatever they want however they can in and around their pain or recovery. I am not advocating that we can just do this in suicide prevention and hope that people do not take their lives, but I am purposing that we look at our work in new ways that help us be more honest with the realities we are faced with, the limitations that exist in our field, and in ways that focus less on the things that are not working and more on the things we believe can (e.g., protective factors and to some degree warning signs).

In all of my years in clinical and professional practice I have worked with amazing, talented, smart, compassionate, and caring people. I have watched them use “tried and true” practices as they tried to determine if someone was at risk of harm to themselves or others. By far, most of the time the person did not go onto attempt and fewer died by suicide. As much as I would love for that to be the outcome because of their work, it is hard to know definitively what kept all of those people alive. I believe we all need to do everything that we can to help save lives, no matter what that is. No tests, no checklists, no scales. No calling in a specialist, no straight admission to a mental health unit. It could be as simple as sitting with someone and letting them know that you care, because until we have figured out how to prevent suicide, compassion might just be the best tool in our toolbox.

Abstract

More than one hundred thousand persons are dying by suicides every year in India. According to the World Health Organization and International Association for Suicide Prevention (IASP), suicide is preventable. Due to social stigma attached with the mental illness in India, suicide prevention awareness campaign is a very difficult task. Indian people are religious minded; therefore, life skills

dynamic meditation gatekeeper training has been developed in the Kachchh district of India, and people participated voluntarily without hesitation and trained for the ten life skills recommended by the World Health Organization with meditation techniques, warning signs of suicide and intervention techniques.

Keywords

Suicide prevention · Life skills · Meditation

Introduction

Life skills dynamic meditation is a conscious awareness of life skills, which are essential for coping with negative aspects of stress in any circumstances, and involves goal-orientated thoughts and behaviours with needful change in the negative attitude and lifestyle for the purpose of peace and happiness by physical, mental, social and spiritual development, through obtaining knowledge of cognitive distortion, defence mechanisms of mind and mental illness, including anxiety, depression, warning signs of suicide, etc., and learning physical exercises, meditation, relaxation techniques and yoga.

Life Skills Dynamic Meditation

In the present chapter life skills dyanmic meditation gatekeeper training for suicide prevention, I am going to explain life skills dynamic meditation process in brief, which has four components: (1) life, (2) skills, (3) dynamic and (4) meditation, with gatekeeper training for suicide prevention. Here, what is life is the very important question, which should be understood first. According to me life is a sum of whole experiences in psychophysiosocial and spiritual plane. The spiritual aspect of life is the most important part of human life, which gives meaning of life with its unique purpose. Since long life has been discussed through religion by the saints, philosophy by the philosophers and biology by the scientists, each person has its own way to define his or her life based on their unique development of personality, normal value, social norms and spiritual experiences obtained through their cultural and religious practices. So, description of what is life is beyond the scope of this present article, but, in short, the point or centre, where all psychological experiences of the mind, physiological experiences of the body, social experiences of the society and spiritual experiences (which are cultivated with personal effort through religious practice) meet to form whole undivided unique experience and, thus, the experienter of this wholeness, is known as the true self of the person (this true self is also known as the soul of the person). Aristotle said that the whole is greater than the sum of its parts. The self is an individual person as the object of its own reflective consciousness; therefore, yourself represents the interacting system of psychological, biological, social and spiritual mechanisms. At the neural and physical level, psychological

concepts refer to the pattern of firing that occupied in the groups of neurons (neuronal circuits). At the physiological level, personality and body make-up are affected by genetics and epigenetics (which depends on neurotransmitters and hormones). At the social level, the person's self-concepts and behaviours depend on the social interactions. Cognitive distortions and intense emotions leading to impulsive behaviours with aggressiveness destroy the social relationship, resulting in family conflicts, divorces, physical violence and crime. At the spiritual level, the person finds a positive way of life, in which he or she seeks to connect to their true nature or to the Divine for having a sense of peace, happiness and purpose in their life, through practising yoga meditation or other spiritual procedures. This is necessary to understand differences between religions and spirituality. Spirituality and religion seem to be the same things, but they are quite different. The specific set of well-organized beliefs and practices done by the people in a specific community and culture is called religion, while spirituality refers to individual practice, leading to peace, happiness and purpose and meaning of life for individual self, and connection with others without any set spiritual values. All religions are helpful for the development of spirituality as the ultimate goal of humankind, but being religious doesn't automatically make a person spiritual or vice versa. Spirituality can be used as a way of coping with environmental changes or uncertainty, like war, epidemic, disasters, etc., as well as personal problems.

Every person wants to be a part of a peaceful happy society and community. Life skills dynamic meditation changes how each person, acting as a single individual, treats others. During the sixth century, Lao Tzu was a Chinese philosopher and author of the Tao-te-Ching, the founder of philosophical Taoism and a deity in religious Taoism. Peace is a concept of societal harmony without aggressiveness, hostility and violence. The following is the quote about peace by Lao Tzu (sometimes also known as Laoze): 3

If there is to be peace in the world,
There must be peace in the nations.
If there is to be peace in the nations,
There must be peace in the cities.
If there is to be peace in the cities,
There must be peace between neighbours.
If there is to be peace between neighbours,
There must be peace in the home.
If there is to be peace in the home,
There must be peace in the heart.

In other words, if we have peace in our hearts, we will certainly build better relationships with others, and by doing so, we all may lead peacefully, healthy and happy life.

In Indian culture shanti path means the path to peace, which is derived from the Sanskrit word "shanti" meaning peace and path meaning the course or direction one is moving. Shanti path is also known as peace mantra, which is a very popular mantra among Indian people. Mantra refers to a word, sound or phrase repeated to

aid concentration in a meditation or prayer. A mantra is given to a trainee meditator when his/her teacher initiates him or her.

Om Sarve Bhavantu Sukhinah
Sarve Santu Niramayah
Sarve Bhadrani Pasyanti ma Kaschitduhkha Bhagbhavete
Om Shanti Shanti Shanti (In Sankrit)

The meaning of the abovesaid peace mantra is that “May all sentient beings be at peace, may no one suffer from illness, May all see what is auspicious, may no one suffer. Om peace, peace, peace. . .”

Long since human beings are thriving for peaceful healthy life, which is a cornerstone for happiness. To have a peaceful happy life, one has to cultivate life skills. Here, skill means the ability to do something well; in other words, skill is the expertise or talent needed in order to do a specific task or job. It is a specific type of work or activity that requires special training and knowledge, which means that skill denotes an ability to do an activity or job well, especially because you have practised it. It is an ability that needs regular practice with patience and positive attitude; therefore, it is a learned ability or capacity for doing a task in an effective manner. Skills concerned with happiness and healthy and peaceful life are known as life skills. Life skills are the means to realize the full potential of individuals. According to the World Health Organization (WHO), life skills are the abilities for adaptive and positive behaviour that enable individuals to deal effectively with the demands and challenges of everyday life.

Psychosocial competence is a person's ability to deal effectively with the demands and challenges of daily routine life. Psychosocial competence is a person's ability to maintain a state of mental well-being and to demonstrate this in adaptive and positive behaviour while interacting with others, his or her culture and environment. Where health problems are related to behaviour and where the behaviour is related to an inability to deal effectively with stresses and pressures in life, the promotion of psychosocial competence is necessary. Psychosocial competence has an important role for the promotion of health in terms of physical, mental and social well-being. The direct interventions for the promotion of psychosocial competencies are those which enhance the person's coping resources and personal and social competencies. In school-based programmes for children and adolescents, this can be done by the teaching of life skills in a supportive learning environment. Life skills teaching promotes the learning of abilities that contribute to positive health behaviour, positive interpersonal relationship and mental well-being. Ideally, this learning should occur at a young age, before negative patterns of behaviour and interaction have become established. Life skills programmes can be developed for all ages of children and adolescents in school. Experience gained in countries where life skills programmes have been developed suggests 6–16 years as an important age range for life skills learning. Life skills are innumerable, and the nature and definition of life skills are likely to differ across cultures and settings. The World Health Organization has recommended ten core life skills, which are listed below:

1. Self-awareness
2. Empathy
3. Critical thinking
4. Creative thinking
5. Decision-making
6. Problem-solving
7. Effective communication
8. Interpersonal relationship
9. Coping with emotions
10. Coping with stress

Self-Awareness

Self-awareness includes recognition of the self, and identifying strengths and weaknesses helps us to recognize when we are stressed. The capacity to understand and care about other people's needs, desires and feelings is known as empathy. Critical thinking is the ability to recognize information and experiences in an objective manner. Creative thinking is a novel way of doing things that generates new ideas. Decision-making helps us to take appropriate decisions. Problems-solving helps us to deal constructively with problems faced in our lives. Effective communication is the ability to express ourselves verbally and non-verbally. Interpersonal relationships denote the ability to make and keep friendly relationships, to maintain good relationships with family members and also to end relationships constructively in a positive way. Coping with stress and emotions refers to the positive coping mechanisms. Coping means to invest own conscious effort to solve personal and interpersonal problems in order to try to master, minimize or tolerate stress and conflict. The psychological coping mechanisms are known as coping strategies or coping skills. The term generally refers to adaptive (constructive) coping strategies, that is, strategies which reduce stress and control emotional contents of thoughts with intelligence. In contrast, other coping strategies may be called as maladaptive, if they increase stress.

Recognition of one's own psychological state containing feelings, behaviour and personal characteristic traits is known as self-awareness, where one takes oneself as an object of attention with awareness. According to the World Health Organization, "Self-awareness includes our recognition of ourselves, our character, strength, weakness, desire and dislikes. It can help us to recognize when we are stressed or feel under pressure. It is often a prerequisite for effective communication, interpersonal relationship and developing empathy for others."

Self-awareness is a refined cognitive process to understand "who we are," which is a prime focus in the meditation and yoga practice in India. Self-awareness allows self-control by understanding what should and what should not be done. In this way self-awareness process makes people competent to recognize their own limitations. Such people express their opinion clearly without doubt and conflict. According to Duval and Wicklund (1972), "you are not your thoughts, but the entity observing your thoughts; you are the thinker, separate and apart from your thoughts." Unhappiness

is due to imbalance between the perceived self and the real or ideal self. Misperceptions of self leads to discontentment and sadness. It is noteworthy that every person perceived oneself in three aspects as the perceived self, the real self and the ideal self. Perceived self is how a person assesses himself/herself and how he/she thinks others view him/her. The perceived self is the way we see that part of ourselves, but it is not real, therefore leading to misperception of self. In other words, real self is the way we would like to be. Your real self is who you actually are, while your ideal self is the person you want to be. Learning from your life experiences, your role models and social demands all together coordinates ideal self. Carl Rogers was a humanistic psychologist, who believed that every person could achieve their goals and desires in life; when, or rather if, they did so, self-actualization took place. Humans have one basic motive: the tendency to self-actualize, i.e. to fulfil one's potential and achieve the highest level of "human being" we can. In other words, self-actualization occurs when a person's ideal self (i.e., who they would like to be) is congruent with their actual behaviour (self-image). Self-image is the way you think about and view yourself. With a positive self-image, we recognize and own our assets and potentials while being realistic about our liabilities and limitations. With a negative self-image, we focus on our faults and weaknesses, imperfections and failure. Because self-actualization involves a strong sense of purpose and self-awareness, it can be a challenging goal to achieve. In short self-awareness is the capacity for introspection and how your actions, thoughts or emotions do or don't align with your internal standard.

Self-awareness means knowing your values, personality, needs, habits, emotions, strengths, weaknesses, etc. Key areas for self-awareness include characteristic traits of our personality, personal values, habits and emotions and the psychological needs that drive our behaviours. Personality is defined as the characteristic sets of cognitions, emotions and behaviour patterns that develop from biological patterns that develop from biological and environmental factors. We can find situations in which we will adjust, and we can avoid other stressful situations through self-awareness process. We focus on our personal values too much by neglecting other responsibilities, e.g., if our priority is business, then we lose insight of our other priorities connected with daily responsibility of our family, friends, workshop, exercise, etc. A habit is a routine of behaviour that is repeated regularly subconsciously. Habit means a recurrent unconscious behaviour pattern acquired through frequent repetition, which may be good or bad, e.g., brushing teeth every morning is a good habit and addiction is a bad habit. According to the European Journal of Social Psychology (2009 study), it takes 18–254 days for a person to form a new habit, and it takes 66 days (more than 2 months) for a new behaviour to become automatic. A book *Psycho-Cybernetics* published in 1960 by Dr. Maxwell Maltz described that it requires a minimum of about 21 days for an old mental image to dissolve and new one to gel. It takes 21 days to fully form a new habit, as 21 days is the time required for new neuropathways to be fully formed in your brain. Brain circuits take engrams (memory traces) and produce neuron connections and neuropathways, only if they are fired for 21 days in a row. This means that our brain does not accept new data for a change of habit unless it is repeated each day for 21 days (without missing a day). This 21-day trail is not limited to good habits – you can use it to break bad habits such as procrastination, binge eating, sleeping late, smoking, biting nails or spending too much on social media.

Self-awareness helps us to evaluate our psychological needs to know which needs exert the strongest influence on our own behaviour to understand how they affect our interpersonal relationships, e.g., people who have a high need for status are attracted to seek high-status positions within their organizations. Such people need costly cars and other things that symbolize their status. Such needs cause motivation, and unsatisfied needs cause anger, frustration and depression. Maslow's hierarchy of needs is a motivational theory comprising five basic human needs, such as physiological needs, safety needs, belongingness and love needs, esteem needs and self-actualization.

Self-awareness of emotional state is one of the five aspects of the emotional intelligence; understanding your own feelings, what causes them and how they impact your thoughts, behaviour, decisions and performance is emotional self-awareness, which is the ability to recognize and understand one's own emotions.

Self-awareness is a self-reflection process where we can understand who I am and what I stand for, so we can objectively evaluate our thoughts, feelings and actions. Know what he or she wants and why. Self-awareness is the foundation to developing your emotional intelligence and the key to open the door of success. An interesting way of developing self-awareness is to use SWOT. SWOT analysis is a strategic planning technique used to help a person or organization identify strengths, weaknesses, opportunities and threats related to business competition or project planning. SWOT is an acronym that stands for strengths, weaknesses, opportunities and threats. SWOT analysis is a framework for identifying and analysing the internal and external factors that can have an impact on the viability of a person, place, product or project. In other words, SWOT analysis focuses on the internal and external environments, examining strengths and weaknesses in the internal environment and opportunities and threats in the external environment. After SWOT analysis a person actively promotes the identified strengths, minimizes weaknesses through proper planning, uses the opportunities before it goes and minimizes threats before they arise.

Empathy

Empathy is the ability to understand and accept others by putting oneself in the other person's place or situation and to understand what he or she is going through and experiencing the emotions, ideas or opinions of that person. In other words, empathy is an awareness of other's feelings, needs and concerns. Empathy is a key element of emotional intelligence. Sympathy is a "feeling for" someone, but empathy goes far beyond sympathy. Empathy is "feeling with" that person. Empathy is a skill that can be developed. There are three types of empathy:

- (a) Cognitive empathy: It is understanding other person's thoughts and emotions, in a very rational rather than emotional sense.
- (b) Emotional empathy: It is catching someone else's feelings, so that you literally feel them too.
- (c) Compassionate empathy: It is understanding someone's feelings and taking appropriate action to help. Compassion recognizes the "me" in "you."

Differences between sympathy and empathy are as follows:

Sympathy	Empathy
1. Evaluating or judging	1. Non-judgemental
2. It is a shared feeling of sorrow, pity or compassion for another person, e.g., when a family member of someone died, you may share a feeling of sadness with him or her, but you might not have empathy for his/her situation if you have not experience or cannot imagine experiencing a death in the family	2. It is much stronger than sympathy because after putting yourself in the place of another and understand his or her feeling with the process of identification, e.g., without empathy a person may fail to understand why another person is feeling sad or angry over a situation. If he or she cannot imagine themselves in that person's place
3. Less active while listening	3. More active while listening

When a person consistently lacks the capacity to sympathize or empathize, i.e., the ability to understand other's problems, then such person is known as narcissistic or in other cases psychopathic. On the other hand, some people are too much empathetic and can eventually be overwhelmed by the negative feelings they receive from other people. Both sympathy and empathy imply caring of other person, but with empathy, the caring expanded by feeling the other person's emotions. It is noteworthy according to Robert Bolton's people skills the empathic person feels the other people's anger, fear, disgust, bewilderment or love "as if" it were his own feeling, but he does not lose the "as if" nature of his own involvement. In yoga psychotherapy process, empathy is a psychological strategy that helps caregivers to offer support to patients suffering from strong emotions. Children learn empathy from watching our behaviours towards family members and others and from experiencing our empathy towards them. When parents empathize with their children, they develop trust and feel secure attachments with their parents. These secure attachments are prerequisite for their desire to adopt parent's values and to model parent's behaviour and therefore to developing their empathy to others.

Critical Thinking

Critical thinking is the ability to analyse information and experiences in an objective manner to form judgement for improvement. Critical thinking is also called critical analysis, which means making clear rational judgement. According to the National Council for Excellence "Critical thinking is an intellectually disciplined process of actively and skillfully conceptualizing, applying, analyzing, synthesizing, and/or evaluating information gathered from, or generated by, observation, experience, reflection, reasoning, or communication, as a guide to belief and action." People who think critically consistently attempt to like rationally, reasonably and empathically. The following are the major components of critical thinking:

- Reflection
- Acquisition of information

- Analysis
- Creativity
- Decision-making
- Commitment
- Structure arguments
- Debate

Much of our thoughts is biased, distorted, partial, uninformed or prejudiced. The quality of what we build, produce or make provides quality of our life, which depends on the quality of our thought; therefore, by identifying and challenging our cognitive distortions, excellence in thought can be cultivated. Critical thinking is self-directed, self-disciplined, self-monitored and self-corrective thinking. Critical thinking is a specific type of thought making procedure about any subject, content of information, or problem, where quality of thinking is improved by analysing, assessing and reconstructing it skilfully. To think critically, one must learn skills that build upon each other. Only by concentrating on and practising these basic skills can mastery of critical thinking be cultivated. To analyse thinking, one should identify its purpose and ask questions about different aspects of the topic: what, how, when, why, and what if, as well as its information, interferences, assumptions, implications, main concepts and point of view. To assess thinking, one should check it for clarity, accuracy, precision, relevance, logic and significance.

The following are the five stages of the process of creativity:

- (a) Preparation stage: It is the idea of preparation, where you gather materials and conduct research that could provide an innovative idea. Here, your brain uses past experiences and knowledge from its memory bank to generate original ideas.
- (b) Incubation stage: All the information obtained in the preparation stage suddenly goes back in the subconscious level of the mind. You are not consciously trying to work on your idea, e.g., you get the idea of writing a book and you start writing, but after sometime you just leave it to the side for days, weeks or months or sometimes even years. How long incubation stage will take can't be predicted. During this stage, your story or problem is incubating in the back of your mind.
- (c) Illumination or insight stage: It is the idea of the "aha" moment, the "eureka" moment. The mental light bulb clicks on, when all gathered material spontaneously comes together to provide the solution to your problem.
- (d) Evaluation stage: Here, you consider the validity of your idea and weight it against alternative options. You reflect back at your initial concept or problem. This stage provides time for self-criticism and reflection, e.g., you ask yourself, "is this a novel idea, or is it that is just rehashed and has been done before?" You also ask your friends about their idea to know what they think about it. You reflect to say, "my ideas have merit and I am going to work on them."
- (e) Verification stage: It is the final stage of the creative process, where you are actually doing the work. This is where Thomas Edison said that "Genius is one percent inspiration and 99 percent perspiration"; your creative product might be a physical object, an advertising campaign, a song, a book, a theory, an architectural design or a martial art – any item that you have created. Now, you finalize your design, bring

your ideas to life and share it with the world. This is also known as the elaboration stage.

We face problems and situations in our daily routine life and respond automatically; we forget to evaluate them for better solutions, and as a result our decisions are affected by our emotions or other external influences. We build our cognitive thinking based on previous similar situations or experiences. Therefore, critical thinking tends to build a rational mindful process, which prevents jumping directly to the judgement. The following six steps are recommended to achieve critical thinking:

- (a) Knowledge/information: Questions should be asked to acquire knowledge about the problem, e.g., what is the problem and why do we need to solve it? By asking such questions, we can obtain a deep understanding about the problem. If there is no actual problem, then there is no need to go through the other steps of critical thinking.
- (b) Comprehension/understanding: Comprehension means understanding what you have heard, seen or read. The data is collected about the situation and the facts concerned with the problem. You make the new knowledge that you have acquired with your own efforts by relating it to what you already know. After comprehension a person can explain what he or she has heard or read into their own words.
- (c) Application usage: After knowing what information you have and what you have comprehended, you carry on specific tasks to apply for situation.
- (d) Analysis: Here, the situation is analysed to identify the strong and weak points and the challenges faced while solving the problem.
- (e) Evaluation/synthesis: Here, you form a decision whether you can give or withhold belief to tackle the problem and whether or not to take a specific action. In this step, you are ready to appraise all the concerned information and analysis to decide the future mode of action towards problem-solving of the comprehended situation for better useful results.
- (f) Creating/taking action: The results obtained through the above steps should be transferred into action. If the decision involves a specific project, a plan of action should be implanted, which indicates that the solution is developed, adopted and delivered as planned.

In short critical thinking involves the following information:

Information – Can you remember the information?

Comprehension – Can you explain ideas or concepts?

Application – Can you use the information in a new way?

Analysis – Can you distinguish between the different parts?

Evaluation – Can you justify a stand or decision?

Creating – Can you create new product or point of view?

The following are the well-known strategies used to develop critical thinking among the students:

- (a) The teacher gives homework for writing assignments, which allows the students to think deeply about their task.
- (b) The students are allowed to explain after studying the matter, and the teacher acts as a facilitator promoting learning, which is known as conference-style learning.
- (c) Having some kind of ambiguity allows students to think critically.
- (d) Asking questions like what you have learned from today's lesson develops critical thinking in the students. It is known as classroom assessment technique used by the teacher.
- (e) The students are allowed for a discussion or present a case study in the classroom and think their way to conclusion.

Creative Thinking

Creative thinking means thinking outside the box; therefore, creative thinking is the ability or skill to imagine something new and meaningful. It is not the ability to create out of nothing but the ability to generate new ideas by combining, changing or reapplying existing ideas. Creative thinking when used to face challenges in daily routine life is known as a life skill. Creative thinking means finding solutions beyond our usual way of reacting to a problem, are based on our past experiences. Creative thinking is the ability to see a problem from a new perspective. It helps us to discover new and better ways of problem-solving. Creative thinking is a necessary prerequisite needed for the development of self-growth and self-actualization. Creative thinking can

be developed either by an unstructured process such as brainstorming (the process for developing unique solutions and ideas through spontaneous and freewheeling group discussion, where participants are motivated to think deeply and suggest all their ideas without hesitation) or by a structured process such as lateral thinking (a systematic process of thinking that leads to logical solutions from completely different angles).

Critical thinking and creative thinking are both different in many aspects. Creative thinking is a way of looking at problems or situations from a new perspective to create something new or original, while critical thinking is the logical, sequential disciplined process of rationalization, analysis, evaluation and interpretation of the information gathered from observation, experience or communication for developing informed judgement and decision. The following are the main differences between critical thinking and creative thinking:

Critical thinking	Creative thinking
1. Critical thinking is a process to assess worth or validity of something that already exists	1. Creative thinking is a process to create something new generative
2. Analytic	2. Intuitive
3. Logical	3. Right-brain function
4. Left-brain function	4. Imaginative
5. Sequential	5. Subjective
6. Objective	6. Non-judgemental/suspended judgement
7. Judgement	7. Visual
8. Verbal	8. Lateral
9. Vertical	9. Fantasy based
10. Reality based	10. Achieved by disregarding accepted principles
11. Achieved by applying accepted principles	11. Pattern seekers
12. Pattern users	12. Hypothesis forming
13. Hypothesis testing	13. Divergent
14. Conversant	14. Open-ended problem-solving
15. Close ended	

Decision-Making

Decision-making is regarded as the cognitive process, which leads to the selection of a course of action or belief among several alternatives. After gathering all information about relevant alternatives, a person can make an appropriate choice; therefore, decision-making is a choice of what to do and what not to do.

First of all, accept the problem, and define it by taking enough time to think rationally. If needed, take advice from family members, friends and others who are concerned with you. List all the advices for understanding them with consideration of family values and ethics. Find other alternatives for consideration, and choose the best by considering the possible effect. Now, you can make the decision for action. If needed, modify your decision or accept the responsibility.

The following are the seven steps to effective decision-making:

1. Identify the decision: Ask yourself why you need to make a decision. What is the nature of the decision?

2. Gather relevant information: You can get internal information through a process of self-assessment and external information available from other people, books and other sources. Collect concerned information before you make a decision.
3. Identify the alternative ways through imagination and other information.
4. Imagine possible impacts of each alternative, and place them according to your priority.
5. Select or choose the best alternative for yourself.
6. Take action to implement the alternative you choose.
7. Review your decision and its consequences: Imagine the possible consequences of your decision, and evaluate whether or not it has resolved the need you identified in step 1. If your decision does not meet your identified need, you can proceed to making a new decision to meet your identified need. For example, you may need to gather more information or explore additional alternatives.

Decision-making is the cognitive process of choosing between two or more models of actions as a solution exactly needed for the problem-solving.

Problem-Solving

A problem happens when an obstacle appears, which makes it difficult to achieve a desired goal, purpose or objective. Such problems when unattended can lead to stress and other mental illness, like anxiety disorder, depression, etc. Problem-solving makes a person to deal constructively with their problems in life, and in this way it enables them to convert their problems into opportunities. In our daily routine life, several problems arise due to a situation, person or thing that needs attention and needs to deal with or solved. When problems arise, we get uncomfortable and run away, or we blame someone. We don't need to solve our problems with right answers here. Problem-solving helps us to get the right solutions for our problems. Problem-solving

is the act of defining a problem, identifying and selecting alternatives for a solution and implementing a solution. Problem-solving process involves the following steps:

1. Identify the problem.
2. Problem analysis: Explore information and create ideas through brainstorming.
3. Choose the best idea.
4. Build and test the idea.
5. Evaluate the results for future consequences.
6. Generate possible solutions.
7. Solution analysis.
8. Solution implementation: Develop at least three alternative plans of action, and set date for implementation of the best plan, which you have chosen.
9. Learning phase: Monitor outcomes of your action, and carry on the problem-solving process if needed.

Steps of problem-solving

Effective Communication

Your innovative ideas fail, if you fail to communicate your ideas effectively in a way that inspires people to accept you with your ideas. Effective communication is about understanding the emotions and intentions behind the information sent and received. We communicate with others and transmit our thoughts and emotions to them by speech, writing, signals and behaviour, so that our message is received successfully by the receiver and understood what the speakers truly mean. Therefore, every interpersonal communication involves senders and receivers to exchange information through a medium. A channel or system of communication is a medium in the effective communication process. The plural form of medium is media, which is also called communication channel or in simple language we call it channel, which transmits message or information between a speaker or writer (the sender) and an audience or reader (the receiver). The media range from individual speech, writing and body language to newspapers, radio, television and the Internet, which represents a form of mass communication. The exchange of views and ideas with expression of emotions, such as anger, disgust, fear, love, compassion, joy, etc., is nothing but communication. A sender is a person who speaks, and a receiver is a person who listens to the speaker. Effective communication is nothing but the exchange of views and ideas with an emotional expression by the sender in an appropriate way, understandable by the receiver. In other sense, effective communication is a process of exchanging ideas, thoughts, information and knowledge, in such a way that the purpose or intention is fulfilled in the best possible manner; therefore, just delivering the message is not enough: it must meet the purpose of the sender. Effective communication is about understanding the emotions and intentions behind the message and to know what the sender really means. If the body language of the sender is not matching with his/her statement, then the receiver doesn't believe in the sender's statement. Much of any message is communicated non-verbally.

Non-verbal communication includes eye contact, posture, body movement, face expression, tone and pitch of the voice and physiological changes that suddenly occur as a result of fight or flight response of stress due to adrenaline rush into the body as a result of negative emotions of anger, fear and low level of confidence. However, an awareness of both negative and positive emotions is necessary for the development of effective communication. This understanding of our own and other's emotional state is known as emotional intelligence. Effective communication does not mean forcing your opinions on others and winning an argument, but effective communication always begins with understanding the other person by allowing him/her respectfully to talk freely, so that the other person feels heard and understood. We often forget to listen to others and jump to conclusions between the communications, therefore neglecting the motive of the message. It is very common to see that while communicating with others, we often focus on what we should say rather than patiently listening to others. However, effective communication means less talking and more listening. Actively listening means understanding the emotions the speaker wants to convey with the words.

The following are the common barriers of effective communication:

- (A) Lack of focus: When you are multitasking and distracting your mind by frequently checking your mobile phone, wandering in daydreaming or thinking what you are going to say next, then you miss the non-verbal components in the conversation, making your communication process weak. Multitasking doesn't allow you to communicate effectively. Therefore, for making your communication effective, you need to avoid distractions of your mind by switching off your mobile phone and stay focus on the present movement.
- (B) Inconsistent body language: Body language should reinforce what is said during communication. Non-verbal communication should not contradict your statement, which you have delivered in your speech in front of the audience. If your statement does not match your body language, then your listener will think that you are not honest with your statement, and they will not believe you.
- (C) Negative body language: During communication a stage comes when you disagree with what's being said and you suddenly response by avoiding eye contact or crossing your arms, which put the person on the defensive mood. For effective communication be aware of your negative body language (e.g., tapping your feet), and control it to avoid sending negative signals.
- (D) Out of control emotions: You feel emotionally overwhelmed during stress; therefore, you misunderstand other people and misread them through your distorted perception and send confusing non-verbal signals through your negative body language and irrational behaviour, which are not socially accepted. Before communicating to others, you should learn to manage your stress to avoid misinterpretation of situation and conflict. Practise deep breathing exercise to learn to calm down quickly during the communication period. An aggressive person can be cool down by listening in an attentive way and making the person feel understood and valued. When such person feels heard and understood, he/she opens his/her heart to build a relationship with you. A person's feeling is expressed through emotional behaviours, e.g., when a person who feel angry shout at you, here, your engaged listening rather than your rational arguments will help him/her to calm down. During arguments you may say something for which you will regret later. Many times we felt stressed during a disagreement with our life partners, children, friends or co-workers and said or did something we later regretted. After learning stress management, we can respond rationally and also help them to calm down quickly.
- (E) An inappropriate medium when used for communicating a message will act as a barrier to effective communication.

Interpersonal Relationship

Interpersonal skills are social skills that you need and use to communicate and interact with your family, friends, customers, co-workers, romantic partners and other people to develop effective interpersonal relationships. A strong bond between

two or more people refers to interpersonal relationship, which can be developed between a man and a woman, father and son, seller and customer, boss and workers, etc. The persons in an interpersonal relationship should have common goals with more or less similar interests and think on the same line; therefore, people having similar backgrounds develop interpersonal relationship more easily. A sense of respecting each other's views and opinions, trust, loyalty and commitment is an essential prerequisite for the development of interpersonal relationship to avoid conflicts and misunderstandings, without any personal bias or prejudice; accepting others as they are with their strength and weakness is necessary for developing interpersonal relationship. Having positive interpersonal relationship with your life partner, customers, friends, co-workers, children, parents and other people has been found to improve your psychological health and well-being. Poor interpersonal relationships have been associated with stress and affect mental health adversely. That is why it is important to have positive people around you, who provide you with support, comfort and joy. It is also necessary to avoid negative people because they don't like to develop, and this is why they want to discourage you from developing as well. The people around us form our personalities and value systems with a core belief, and they provide us with purpose and direction.

According to psychologist George Levinger, there are five stages of interpersonal relationships as follows:

Stage 1 (acceptance): We meet many people but feel attractions towards those who are beautiful, supportive and honest.

Stage 2 (build-up): By revealing our personal likes and dislikes, we become more and more independent; therefore, whenever two people are involved in an interpersonal relationship, they show increased level of trust and comfort with each other. During the build-up stage, an adviser role is possible to influence the decisions and actions of a co-worker and client. People involved in the build-up stage not only act as a co-worker but also as a friend. In the build-up stage, you have to know the other person personally and use your influence sparingly and positively. Engaging in abuse of the privileges of your friendship can quickly lead to its degradation or dissolution (i.e., stage 4, deterioration).

Stage 3 (continuation): First of all, people get together and build up relationship; then, they enter to the continuation stage by making long-term commitments and maintain relationships with family, friend and customers. In the continuation stage, there is a feeling of trust and commitment to the relationship and a corresponding increase in the amount of influence both people can exercise. This is where you will reap the benefits of better communication, improved productivity and an increased satisfaction with work. Increased effort is needed to maintain the relationship, and this increased effort comes with the increased trust and influence. It is noteworthy that without maintaining effort, the relationship starts deteriorating (i.e., stage 4, deterioration), leading to a return to the acceptance stage (stage 1) or termination stage (stage 5).

Stage 4 (deterioration): Many relationships decay due to several factors. It is a necessary phase because no one works in the same job forever and circumstances

frequently lead to a change in the frequency of contact. Without paying special effort and attention to its maintenance, the relationship can revert back to the acceptance stage (stage 1) in the personal relationship continuum.

Stage 5 (ending): The relationship ends when partners agree to separate or one leaves. It is extremely unlikely that you will remain in contact with everyone you meet throughout your entire professional career, and so termination will be a natural step in many of your workplace relationships. It is important to understand the stage of the relationships you are in. If you want to sustain them, act to prevent deterioration by paying special effort and attention to the maintenance of the relationship through get-together in parties, meeting and social functions. If you are too busy, then maintain the relationship by using social media. If you want to end your relationship, then get through the deterioration as soon as possible.

Successful interpersonal relationships get to the continuation stage (stage 3) in the personal relationship continuum. They may last until death do us apart. Some relationships are maintained for a limited time only. There are some interpersonal relationships with neighbours, friends of friends and others you interact with on a semi-regular basis, where relationship doesn't progress beyond the acquaintance stage (stage 1). These are known as secondary interpersonal relationships. Here, you may exchange "hellos" and "how are you."

Relationships require effort, and no relationship is 100% perfect; therefore, conflict happens. When conflict arises, both sides have to work to maintain a positive connection through maintaining clear and open communication by talking and listening, which will form a strong bond and resolve conflicts.

You have to maintain the following relationship habits:

- (a) Be honest and trustworthy because, without trust, there is no relationship.
- (b) Listen to each other.
- (c) Respect each other.
- (d) Be slow to judge.

You can improve your interpersonal skills by developing your awareness of how you interact with others and practising your skills.

Coping with Emotions

Coping with emotions means healthy ways to cope with negative emotions generated by the feelings of sadness, anger, frustration, fear, loneliness, anxiety or low self-esteem. Learning to deal with these emotions in a positive way makes your life healthy and happy. The following are methods to calm yourself down when you are feeling overwhelming emotional challenge:

1. When your body becomes tense due to stress and you are charged with negative emotions, then, first of all, let your pent-up negative emotions released physically

through walking for a long distance, screaming in front of a mirror, punching into a pillow, squeezing a stress ball, playing outdoor games, crying, singing, dancing, etc.

2. You can also express your negative emotions through involving yourself in creative works, e.g., drawing, writing a diary, writing a poem, making a scrapbook, playing musical instruments and knitting. Studies have shown that repetitive actions involved in crafts like knitting, crochet and needlework can release stress and induce a state of deep relaxation, similar to that we experience during well-known relaxation practices, like yoga and meditation. Those who have learned knitting are expected to experience a lower heart rate, lower blood pressure and reduced cortisol level. The repetitive activities of knitting have been shown to activate the parasympathetic nervous system, which quiets the fight or flight response of stress, so people feel calmer, quieter and more relaxed.
3. You can express your negative feelings and thoughts by talking with someone you trust like family, friends and counsellor.
4. Relaxation coping strategies help our mind and body to refocus by practising deep breathing technique, yoga, meditation and muscle relaxation process.
5. You can calm yourself down by doing make-up, listening music, having a hot water bath or cuddling a pet, pillow or toy.
6. Powerful negative emotions are too difficult to express in other ways; in such circumstances, try to distract your mind by watching a movie or TV, looking at funny videos, calling friends by phone, doing something you enjoy and learning new things. Here, distraction of your mind is keeping yourself busy to take your mind off the issue.
7. Emotions play a key part in your reactions towards events or situations created by other people in this world. When you are in tune with your emotions, you have access to important knowledge that helps with self-care, interpersonal relationship, decision-making and day-to-day interactions. Uncontrolled emotional responses spoil interpersonal relationships. Any emotion, whether it is positive or negative, can intensify to a point where it becomes difficult to control; therefore, one should learn to control any excess of emotions. Coping with emotions means recognizing emotions within us and others and being aware of how emotions influence behaviour. We should be able to respond to emotions appropriately in a socially accepted way. Intense emotions like anger, fear or sadness can have negative consequences on our health, if we do not respond appropriately; therefore, it is crucial to learn to control and express our anger, fear or sadness in a constructive manner, which is known as emotional intelligence. Emotional intelligence is the ability to recognize emotions not only inside yourself but also inside of others. The following are four noteworthy terms concerning emotional intelligence:
 - (a) **Self-awareness:** It refers to understanding and noticing your emotions.
 - (b) **Self-control:** It refers to the ability to control your own emotions.
 - (c) **Empathy:** It refers to understanding the emotions of others.
 - (d) **Social skills:** It refers to the ability to influence the emotions of others.

Through emotional intelligence, emotional stability refers to a person's ability to remain calm in daily life circumstances when faced with pressure or stress. An emotionally unstable person faces an increased risk of reacting with violent or harmful behaviours when provoked.

Whether it's a chaotic work environment or family problem, we all have those moments when we feel emotionally out of control. Actually, our minds feel what we decide they feel. With the presence of mind in the present moment and a bit of practice, being emotionally stable is achievable in any circumstances.

Emotional stability starts with you; you need to learn to control the way you feel and not let people control it for you.

Controlling your emotions is a skill that takes practice, awareness and a lot of discipline and self-control, but it can be done.

Suicide Prevention in India

In India suicide is the most common cause in both the age groups of 15–29 years and 30–44 years. Mental health awareness campaign for suicide prevention is a very difficult task due to increased level of stigma attached with mental health issues, particularly in India. After a several years of field experiences, life skills dynamic meditation gatekeeper training for suicide prevention has been developed in the Kachchh district of the Gujarat State in India, where sociocultural background of the Indian people has been considered. Life skills dynamic meditation training seminars and workshops have been organized in several places of India with good public participation. In India, there is a lack of effective life skills training in schools and colleges. In India, adults who have not been provided Life Skills training opportunities, now they have been provided with life skills dynamic meditation training for suicide prevention, where ten core life skills recommended by the World Health Organization along with meditation, deep breathing pranayama technique, yoga postures, warning signs of suicide and methods of timely interventions have been included.

Life skills dynamic meditation is a conscious awareness of life skills, which are essential for coping with negative aspects of stress in any circumstances, and involves goal-orientated thoughts and behaviours with needful change in the negative attitude and lifestyle for the purpose of peace and happiness by physical, mental, social and spiritual development, through obtaining knowledge of cognitive distortion, defence mechanisms of mind and mental illness (e.g., anxiety, depression, warning signs of suicide, etc.) and learning physical exercises, meditation, relaxation techniques and yoga.

What Is Stress?

Stress is our body's normal psychological and physical response to the challenge or threat.

Stress is built up when external pressure or demand of the situation exceeds personal resources, e.g., lack of time to prepare for interview, lack of money and lack of support of family members and friends. Stress is built up when external pressure exceeds the resources.

$$\text{STRESS} = \text{PRESSURE} > \text{RESOURCE}$$

You cannot control the outer world (which depends on time, money, family and friend's help), but you can control your inner attitude. When we consider our attitude in the list of personal resources which you can control in every circumstance, then we find that

$$\text{STRESS} = \text{PRESSURE} > \text{ATTITUDE}$$

Now, considering this formula which we have obtained, in other words we can define stress as losing touch with the power of attitude. If we change the attitude from negative to positive, then we find that stress is decreased or controlled.

$$\text{STRESS} = \text{PRESSURE} < \text{ATTITUDE}$$

What Is Attitude?

A feeling or a way of thinking that affects behaviour is called attitude.

Attitude is the way you think and feel about something.

How you think and what you think build your attitude. If you think in a positive way, then your positive attitude leads to peace and happiness in your life, but if you have negative thoughts running inside your head, then your negative attitude will create stress that may lead to anxiety, depression and sadness.

What Is Dynamic?

Literally, dynamic means positive in attitude and full of energy and new ideas of a person.

Most stressful situations benefit from a calm, rational, controlled and socially sensitive approach.

Calm mind keeps the fight or flight response of stress under control. Consciously creating a calm mind is a dynamic process. Therefore, coping with stressful situation with consciously focusing your attention to create a calm mind is known as dynamic calm mind. Your dynamic calm mind uses your energy wisely and does not waste your energy through fight or flight response of stress.

The acute stress response is a physiological reaction of the body in the presence of danger, which is also known as fight or flight response of stress. Our ancient ancestors had faced danger of the forest with their fight or flight response. In stressful circumstances the sympathetic nervous system of the body gets activated to release adrenaline and noradrenaline from the stimulated adrenal gland, resulting in increase in heartbeats, breathing rate and blood pressure. When the danger has passed, the body returns to the pre-arousal levels within 20–60 min. Fight or flight response can be triggered due to both real physical dangers and imaginary psychological threats. Fight or flight response plays a critical role for survival in the life-threatening situations. Understanding of fight or flight response helps us to cope better with irrational fear and anger.

When your mind is devoid of fear or anger, then only your mind is fully clear from the past or future and only you can focus your mind very easily and naturally on your present moment to solve your daily life problems positively. But when the fear or guilt of the past and worry of the future make your mind cloudy, then you cannot focus your mind on the present moment.

What Is Meditation?

We can define meditation in several ways. One way is through sitting quietly by closing eyes with turning attention inward by focusing awareness on thought, image, conscious breathing is known as meditation.

The conscious practice of awareness about daily life activities mindfully is known as meditation. Meditation refers to any conscious activity that keeps the attention focused peacefully on the present moment. Meditation refers to know what I am feeling inside and how we react on events outside and understanding who I am.

Meditation may also be done in an active way, e.g., Buddhist monks involve awareness in their day-to-day activities as a form of mind training.

These are different ways of meditation, depending on the different teachers and traditions, but all types of meditation involve silent observation of non-judgemental thoughts without interpretation. Life skills dynamic meditation includes techniques designed to promote relaxation, build internal energy (prana), remove fear and develop compassion, forgiveness, generosity, love and patience. In meditation the choice of focusing your mind in something needful depends on you. When you make a conscious choice to focus your attention on something purposeful in the present moment, then only you become aware. So, awareness is needed to become witness of your thoughts.

Life skills dynamic meditation training involves the following:

- (A) Lifestyle change: In life skills dynamic meditation training, positive lifestyle changes are recommended for appropriate diet and exercise, including anger, conflict and time management.
 - Eating healthy food: Eating three times a day is recommended. Unhealthy food habits should be stopped, including substance abuse (stop smoking, alcohol, tobacco chewing, drugs, etc.).
Note: People drink permitted amount of alcohol in Western countries according to their cultural norms.
 - Exercise: Exercising up to 50 min daily is recommended.
 - Eight glasses of water: Drinking at least 2 l of water (8 glasses) daily is recommended.
 - Taking a relaxing break for a short period every day.
 - Effective time management.
 - Effective conflict management.
 - Effective anger management.
- (B) Positive attitude.
- (C) Self-affirmation.
- (D) Relaxation techniques.
- (E) Rhythmic muscular contraction wave generation (RMC wave generation) for 15 min.
- (F) Physical activities: Warm-up exercise and yogasana.
- (G) Breathing exercise (pranayama, kapalabhati)

- (H) Mental activity: Meditation and obtaining knowledge about cognitive distortions, defence mechanisms of mind, mental illness (e.g., anxiety, depression, warning signs of suicide, etc.) and neurotransmitters of the brain.
- (I) Life skills recommended by the World Health Organization.

What Is Depression?

Depression (major depressive disorder) affects how you feel, the way you think and how you act. Depression is the most common serious mental illness and, if left untreated, can lead to suicide. Feeling sad or having a depressed mood, loss of interest, change in appetite and sleeping pattern for the period of at least 2 weeks or more indicate symptoms of depression. Depressed people can feel hopelessness and worthlessness with difficulty in thinking, concentration or making decisions. He/she may be preoccupied with the thoughts of death or suicide. Depression can affect any one, and timely intervention can prevent suicide. Depression is treatable. Any person having above symptoms should be referred to a psychiatrist for the treatment. About 80–90% of people affected by depression generally respond well to treatment, and almost all depressed patients get some relief from their troublesome symptoms.

If people are in trouble time in their life fails to manage their stress level timely, then they feel pervasive sad mood, which may continue for two weeks or more leading to depression. If depression is not recognized timely, then lack of timely intervention may lead to suicide.

People should understand that suicide is preventable. Suicide is intentionally taking one's own life. But by recognizing the following warning signs of suicide, people can actively intervene to prevent suicide:

What Are the Warning Signs of Suicide?

Educating yourself about the warning signs of suicide and how to intervene actively to help someone who is hurting himself or herself can be the first priority for saving the suicidal person's life. Early detection of warning signs can lead to a mental health professional help and can save a life; therefore, suicidal warning signs should be taken very seriously. There isn't really any typical pattern of behaviour for someone who is suicidal, but you may easily observe and understand the following warning signs and intervene timely to prevent suicide:

1. Talking of dying or threatens to kill himself or herself
2. Previous suicidal attempts
3. Family history of suicide or suicidal attempt
4. Talking about feeling of hopelessness, helplessness and worthlessness
5. Showing increased anger and aggression and unable to control impulsive behaviour
6. Expressing strong feeling of guilt and shame

7. Preparing a will
 8. Making arrangements for pets
 9. Unusual spending, giving away possessions
 10. Social withdrawal and isolation
 11. Saying goodbye to all
 12. Showing risky activities without thinking
 13. Talking about not having a purpose or a reason to live
 14. Sad mood
 15. Gathering lethal means
 16. Change in appetite and sleep patterns, particularly decreased sleep
 17. Unusual mood swings
 18. Reliving past stressful experiences (Post Traumatic Stress Disorder (PTSD))
 19. Having increased smoking, alcohol or drug abuse
-

What Can you Do if Someone Seems Suicidal?

- Do not leave the person alone.
- If you suspect someone is suicidal, talk to that person privately, actively listen without judgement and be compassionate.
- Ask them directly if he or she is considering suicide because according to the World Health Organization mentioning suicide or discussing it is not going to push anyone over the edge and make them take action.
- Remove potential means of self-harm, including knives, ropes, petrol, pesticides, firearms, etc.
- Take him or her to mental health professionals.
- Contact local suicide prevention helpline.
- If the person is taking psychiatric treatment, help that person to contact his or her therapist for guidance and help.

Complex Trauma and Suicide: An Integrative Interpersonal Approach

Abstract

Complex trauma is a term used to describe traumatic experiences that are chronic, repetitive, and invasive (e.g., domestic violence, captivity, torture). Complex trauma is associated with more pernicious psychosocial outcomes than other forms of traumatic experience (e.g., natural disasters, isolated assaults). Perhaps the most serious of these outcomes include thoughts about, attempts at, and completion of suicide. Theorists have long considered suicide to be an essentially interpersonal act, with fundamentally interpersonal causes and consequences. Similarly, what makes complex trauma *complex* is the interpersonal nature of it, the layering of perpetrations by other people, and interpersonal meanings made in the aftermath of these perpetrations. Although there are numerous parallels in the literatures on complex trauma and suicide with respect to interpersonal factors, these parallels have not yet been made explicit or articulated within an integrative interpersonal framework. In this chapter we will bridge this gap by defining and

overviewing the research on complex trauma, discussing interpersonal approaches to understanding suicide, and providing an integration of the complex trauma and suicide literatures within an integrative interpersonal framework. Based on this integration, we will also highlight directions for future research and potential implications for clinical intervention.

Keywords

Complex Trauma · Interpersonal Theory · Suicide

Suicide is a common problem in the aftermath of experiencing trauma, but not all forms of trauma are equally likely to result in suicide. One especially pernicious form of trauma is complex trauma, traumatic experiences that are chronic, repetitive, and invasive (e.g., domestic violence, captivity, torture). Complex trauma is associated with more adverse psychosocial outcomes compared to other forms of trauma, the most serious of which is suicide. One reason for the link between complex trauma and suicide may be that both complex trauma and suicide share underlying interpersonal dynamics. However, thus far there has been little work laying this out explicitly.

The Interpersonal Theory of Suicide

Toward an Interpersonal Understanding of Suicide

Suicide has been a persistent problem throughout history and across cultures [19]. Accordingly, there have been numerous approaches to understanding suicide, each approaching the issue from a different perspective. Perhaps the earliest theory of suicide was sociological and conceptualized suicide as the result of improper integration or regulation of a person within society [14]. In this view, suicide is the result of someone being too integrated into society (altruistic suicide) or not integrated enough (egoistic suicide) or being too regulated by society (fatalistic suicide) or not regulated enough (anomic suicide). Later theories of suicide emphasized the influence of psychological factors on suicide. One such factor is psychological pain, and many have suggested that suicide is an effort to escape profound psychological pain [25, 27]. Another factor is hopelessness. Specifically, it may not be that discrete forms of dysfunction (e.g., psychological pain, one's role in society) lead a person to end their life, but rather the belief that they are unable to change this dysfunction [3].

Recent efforts to understand suicide have involved integrating both social and psychological factors. Perhaps the most common example of this is the interpersonal theory of suicide [19, 21, 31]. In this view, the combination of two factors lead a person to suicide, thwarted belongingness (the inability to connect with other people) and perceived burdensomeness (the belief that one is a drain on others). Thwarted belongingness corresponds to egoistic suicide in that both involve

detachment from other people. Perceived burdensomeness is in many ways an extension of hopelessness, with a person feeling not only unable to improve his or her own situation, but also feeling as if their inability affects others adversely. In this model, profound psychological pain of the type that leads to suicide is often a consequence of one or both these factors: a person feels bad because they are simultaneously detached from people, believes they are a burden on them, and feels helpless to change this [19].

Research on the Interpersonal Theory of Suicide

There is empirical support for the interpersonal theory of suicide. Meta-analytic research suggests that perceived burdensomeness and thwarted belongingness predict both suicidal ideation and suicide attempts [12]. There is also evidence that these two dimensions interact with each other to have a multiplicative effect on suicide (for review see Ma et al. [24]). For example, high perceived burdensomeness and thwarted belongingness multiply the effects of each other to predict higher suicidality over and above the independent effects of both [30]. Furthermore, thwarted belongingness and perceived burdensomeness interact with acquired capability for suicide (i.e., the ability to kill oneself vs. the desire to do so; see Ribeiro and Joiner [26]) such that higher levels of all three predict suicide attempt over and above independent effects [20].

Evidence for the interpersonal theory of suicide is well established and continues to contribute meaningfully to research on and intervention with suicidality. However, despite research on this model considering potentially traumatic events (e.g., [30]) and samples that have high rates of both trauma and suicidal behavior (e.g., military personnel; see Joiner et al. [20]), there has been little work applying an interpersonal understanding of suicide to the context of trauma. This is especially true in the case of complex trauma, which may be especially predictive of suicide.

Complex Trauma and Suicide

Trauma and Complex Trauma

Trauma refers to an event that challenges a person's fundamental beliefs about the world, others, and themselves ([18, 35]). Trauma is common, with a majority of people endorsing one or more potentially traumatic events over the course of their lives [16]. Although most people who experience such events do not suffer adverse consequences, effects of trauma can be debilitating for others. Research suggests that trauma is associated not only with posttraumatic stress disorder (PTSD; the prototypical outcome of trauma exposure), but also with symptoms of depression, anxiety, and dissociation [7, 15, 29]. Though potentially harmful, not all forms of trauma are equally injurious.

Complex trauma refers to those traumatic experiences that are chronic, repetitive, and entail an intimate, interpersonal perpetration [10, 35–37]. Examples of complex trauma include child abuse, domestic violence, and sexual abuse. For example, child abuse often occurs for a prolonged period of time throughout childhood and is often perpetrated by a trusted person. The continuous and interpersonally intimate aspects of complex trauma make exposure to it more psychologically injurious than more time-limited, less interpersonal forms of trauma (e.g., natural disasters, traffic accidents). For example, symptoms of PTSD and depression in the aftermath of complex traumas are often more severe than symptoms following “simple” (e.g., single event) traumas [10, 13]. Also unlike other forms of trauma, complex trauma is associated with alterations in personality such as reduced ability to regulate affect and inhibit impulses [10, 38, 39]. The problems resulting from complex trauma may thus leave the complex trauma survivor with an inability to cope, which can sometimes be lethal.

Complex Trauma and Suicide

Perhaps the most devastating problem associated with complex trauma is suicide [11, 37]. There are two primary ways by which complex trauma may lead to suicide. First, suicide may be a means of escaping the symptoms associated with complex trauma. For example, symptoms of PTSD and depression are common among and cause distress for people who experience complex trauma, who may attempt suicide to relieve their distress [9, 37]. This is consistent with research suggesting that symptoms of PTSD and depression are associated with suicide [5, 32, 37].

A second way in which complex trauma may be associated with suicide is more direct. Complex trauma is associated with affect dysregulation and impulsivity, each of which may increase suicide risk in and of themselves [5, 23]. For example, people with severe difficulty regulating their affect may resort to suicide and other self-destructive behaviors in an attempt to regain control of themselves [40]. High levels of impulsivity may lead a person to attempt suicide in an effort to solve problems without considering other, less permanent solutions [17]. However, although there is research on the link between complex trauma and suicide, this research is not yet well integrated with the interpersonal dynamics of suicide.

An Integrative Interpersonal Approach to Complex Trauma and Suicide

Interpersonal Theory

Both complex trauma and suicide are interpersonal in nature [28]. Interpersonal theory explains these interactions in terms of two dimensions: warmth is the tendency to be connected with others (versus coldness the tendency to withdraw from others); dominance is the tendency to be assertive and self-assured with respect to others

(versus submissiveness the tendency to be docile and let others take the lead; [6, 22, 33]). The degree to which one person behaves warmly and/or dominantly with another person sometimes also influences how that other person behaves in response. We can predict people's behavior using the principle of complementarity, the idea that one person's behavior follows naturally from the interaction they just had with another person (see [22, 41]). Complementarity works in two ways: people behave comparably in terms of warmth (e.g., if I am nice to you, you will be nice to me, in roughly equal measure) and contrast each other in terms of dominance (e.g., if one person leads [dominant], the other person follows [submissive]). Complementarity with respect to warmth and dominance works in concert with each other. For example, blowing a kiss (warm-dominant) may elicit blushing (warm-submissive), and yelling angrily (cold-dominant) may elicit cowering (cold-submissive).

Interpersonal theorists have developed a way of mapping interpersonal behaviors graphically using a tool called the Interpersonal Circumplex (IPC; Fig. 1; [42]). The IPC is a circle with warmth on the horizontal axis and dominance on the vertical axis. The farther away from the center of the circle the more extreme a behavior is. For example, along the warmth axis just to the right of the IPC's vertex would be a smile, further to the right would be a hug, and even further to the right would be a kiss (see Fig. 2). We can also use the IPC to depict combinations of warmth and dominance. To use an example on the cold side of the IPC, in the upper left quadrant close to the vertex would be a frown, further up and to the left would be a verbal insult, and at even further up and left would be physical assault (see Fig. 2). We can use the IPC

Fig. 1 The interpersonal circumplex (IPC)

Fig. 2 Example behaviors depicted graphically on the IPC

and other tools of interpersonal theory to understand a range of behaviors that happens between two or more people.

Interpersonal Dynamics of Complex Trauma and Suicide

We can understand both complex trauma and suicide in terms of interpersonal dynamics using the IPC. Complex trauma is inherently cold in that it involves a detachment from others and dominant in that it involves an overpowering of another person's agency. For example, domestic violence is an aggressive behavior (dominant) that alienates victims from themselves and their intimate partners (cold). We could thus think about domestic violence and other forms of complex trauma as being in the cold-dominant area of the IPC. In contrast, suicide is the result of thwarted belongingness (cold) and perceived burdensomeness (submissive). We would thus think about suicide as being in the cold-submissive area of the IPC (see Fig. 3).

We can understand the dynamics between complex trauma and suicide using the principle of complementarity. Because complex trauma is cold and dominant, the complementary response to it is cold and submissive. Indeed, this is the case for many common psychological sequelae of trauma in general (e.g., symptoms of PTSD and depression, which are cold and submissive; for review see Yalch and Burkman [35]). However, complex trauma is chronic, repetitive, and otherwise more severe than other forms of trauma, and correspondingly pulls for a more extreme response. The behavior

Fig. 3 Complex trauma and suicide depicted graphically on the IPC

that is at the extreme of cold submissiveness is suicide. In effect, suicide is complementary to complex trauma – and the more severe or repeated complex trauma is, the more at risk for suicide a person may become (see Fig. 3).

Discussion

In this chapter, we reviewed the research on suicide and complex trauma, provided an overview of an integrative interpersonal approach to clinical case conceptualization, and applied this approach to the dynamic association between suicide and complex trauma. Future work can build on this to extend research on suicide and complex trauma and to intervene with survivors of complex trauma at risk for suicide.

The integrated interpersonal approach to understanding the link between suicide and complex trauma has a number of implications for future research. For example, although we conceptualize complex trauma as a cold-dominant experience (and suicide as a cold-submissive behavior), we did not examine this empirically. Future research could thus build upon the framework we propose in this chapter by examining how the experience of complex trauma and suicide “project” quantitatively across the IPC. Although it would be valuable to examine the interpersonal projection of both complex trauma and suicide independently, it would perhaps be of even more value to examine how trauma and suicide relate to each other dynamically over time. Future research could also address this.

There may also be implications for working clinically with survivors of complex trauma at risk for suicide. Clinical intervention with trauma survivors often begins with an assessment of the traumatic experience(s) and symptoms that develop in the aftermath of these experiences [8]. However, given the interpersonal nature of both complex trauma and suicide, assessment of interpersonal style (e.g., one's characteristic way of relating to others, the strengths and problems one has in these relations, how one would like to relate to others) might also be valuable. Specifically, assessment of interpersonal style may provide an indication of whether a client struggles with interpersonal connectedness and or efficacy (or their inverse, thwarted belongingness and perceived burdensomeness), thus providing targets for intervention in addition to discrete symptoms and behaviors.

Assessment of interpersonal style may also inform the process of treating complex survivors. Indeed, several contemporary approaches to psychotherapy [2, 4] begin with an interpersonal assessment so as to inform the therapist how to interact with the patient most effectively. In these approaches, it is useful to complement the patient early in treatment in order to build trust and clinical rapport, but contrast with the patient's interpersonal style later in treatment to pull them (via the principle of complementarity) to try new and adaptive behaviors. For example, in working with a complex trauma survivor who by virtue of their cold and submissive interpersonal profile is at high risk of suicide, a therapist might begin treatment by adopting an approach that is directive and not overly warm, thus providing a safe and familiar environment for the patient. Over time, as trust between patient and therapist grows, the therapist may behave more warmly toward the patient, pulling the patient to being more connected in response (thus reducing a sense of thwarted belongingness). Still later in treatment, the therapist could progressively adopt a less directive and more collaborative approach to therapy, allowing the patient to experiment and feel more comfortable with their sense of autonomy (thereby reducing perceptions of helplessness and burdensomeness). Although this interpersonal approach was developed in the context of treating interpersonal problems characteristic of personality disorders, recent work has shown its efficacy in work with trauma survivors [39]. Future research should examine how this might play out in practice with survivors of complex trauma.

There are a number of limitations to the literature, which suggests directions for future research. One limitation is that although we describe complex trauma as a uniformly cold-dominant experience, the reality may be more nuanced. Namely, some manifestations of complex trauma may be cold but not dominant (e.g., physical and emotional neglect) and others may have more complicated interpersonal signatures (e.g., sexual abuse, which uses intimate connection [an otherwise warm experience] as a means of subduing and aggressing against another person [which is cold-dominant]). The different forms complex trauma take may in turn project differently across the IPC and thus may contribute in different ways to suicide. Similarly, suicide may also be more complicated from an interpersonal perspective. For example, wishing oneself were dead may be more submissive than actively attempting to end one's life (and different methods of ending one's life are likely more aggressive than others; e.g., shooting oneself vs. overdosing on pills). Empirical and theoretical efforts can clarify these issues further.

In this chapter, we overview and synthesize the theoretical and empirical literature on complex trauma and suicide within an integrated interpersonal framework. Future research can further refine these insights, with the ultimate goal to improve clinical practice for survivors of complex trauma at risk for suicide.

Abstract

There is growing evidence that the effects of the COVID-19 pandemic have extended well beyond those who have been infected or bereaved by COVID-19. However, the extent of the effects remains unknown. The public health measures put in place in countries around the world to mitigate the spread of the virus have led to significant disruption to people's lives. In particular, the implementation of lockdown measures which have included restrictions on movement, social gatherings and the closing of all nonessential retail and hospitality, have impacted upon people's sense of isolation and uncertainty [1]. As many of these factors may also be associated with suicidal ideation and suicidal behaviors, in this chapter we review the evidence from before and during the pandemic to better understand the mental health impact of COVID-19.

There is growing evidence that the effects of the COVID-19 pandemic have extended well beyond those who have been infected or bereaved by COVID-19. However, the extent of the effects remains unknown. The public health measures put in place in countries around the world to mitigate the spread of the virus have led to significant disruption to people's lives. In particular, the implementation of lockdown measures which have included restrictions on movement, social gatherings and the closing of all nonessential retail and hospitality, have impacted upon people's sense of isolation and uncertainty [1]. As many of these factors may also be associated with suicidal ideation and suicidal behaviors, in this chapter we review the evidence from before and during the pandemic to better understand the mental health impact of COVID-19.

Previous Evidence from Infectious Disease-Related Public Health Emergencies

Suicidal behavior is one of the most challenging human phenomena to understand. Despite the best scientific efforts to date to understand and predict suicidal behavior, our capacity to forecast its occurrence remains no better than chance [2]. This is, in part, due to its complexity which can be expressed across different levels of analysis spanning the biological, psychological, cultural, and social domains [3]; with the factors within each of these domains influencing each other as a complex system [4]. Indeed, besides the risk associated with the individual level (biological and psychological), the occurrence of suicidal behavior is also affected by issues at community and societal levels, such as unemployment [5], wars [6], inappropriate media reporting [7], natural disasters [8] to name a few. Fully recognizing that suicide risk can be affected by wider societal factors is important as it allows governments and public agencies to plan social, economic, and health policies for suicide prevention, potentially protecting more vulnerable lives.

At the start of the COVID-19 pandemic, concerns about a potential increase in suicidal behaviors and suicide deaths were raised, given the multidimensional impact of the pandemic on the lives of billions of people globally [9]. In light of such concerns, it seems pertinent to investigate what could be learned from previous epidemics/pandemics (infectious disease-related public health emergencies) and their impact on suicidal behavior, self-harm, and suicide. Such questions were addressed in a comprehensive systematic review of the available scientific literature conducted at the beginning of the COVID-19 pandemic by Zortea and colleagues [10]. This review yielded eight primary studies published between 1992 and 2017 and synthesized the evidence on the effects of epidemics that occurred from 1889 to 2016. These epidemics comprised the Great Influenza Epidemic [6], the Russian influenza [11], Severe Acute Respiratory Syndrome (SARS) [12–15], and the Ebola virus disease [16]. The findings indicated a potential association between exposure to infectious disease-related public health emergencies and suicidal behavior, although the authors highlighted the need for caution in the interpretation of the

findings given that many of the studies included in the review were of low methodological quality.

A number of potential mechanisms were identified to explain the relationship between exposure to epidemics and suicide-related outcomes [10]. These included depressive symptoms, anxiety disorders, posttraumatic stress disorder (PTSD), helplessness, fear, unresolved anger, guilt, worthlessness, sleep problems, self-stigma, feelings of entrapment and burdensomeness, substance misuse, loneliness, social isolation, disconnectedness, disruption of everyday routines, unemployment, financial strain/insecurity, domestic violence, and child neglect/abuse. According to the studies in the review, such factors may emerge due to the radical disruptions caused by the pandemic and the typical responses by governments following the occurrence of these events. Gaining insights into the pathways from public health emergencies to suicidal thoughts and behaviors seems to be particularly important to plan interventions that mitigate the increased suicide risk.

However, there was a clear paucity of evidence on the epidemics-suicide relationship. Many critical gaps were identified [10], such as:

- the short- and long-term effects of the association between COVID-19 and suicide-related outcomes;
- the need for monitoring the trajectory of any observed changes;
- the impact on particular populations who are at elevated risk of suicide;
- the association between exposure to the virus, hospitalization, and suicide risk;
- the population-attributable risk of suicide outcomes that arises from factors unique to pandemics including social distancing, mass exposure to a virus with neuropsychiatric health sequelae, in contrast to more general ongoing risk factors such as psychiatric disorders;
- the effect of medical illness and access to means;
- the effectiveness of different suicide-specific population-level interventions;
- the examination of new ways of delivering interventions online;
- the investigation of mechanisms that drive changes in suicide-related outcomes if these occur.

Some of these concerns and research priorities were also raised in several editorials in the early phase of the pandemic [9, 17–20] with the recognition that suicide prevention mitigations should be put in place, given the urgent and pressing needs caused by the potential multifaceted effects of the pandemic [18].

What Do We Know About the Suicide Rates During the Pandemic?

It is too early to tell what the medium and long-term effects of COVID-19 on suicide risk will be. But it is likely that the COVID-19 pandemic and the associated social restrictions will have a long-term detrimental impact upon the mental health and well-being of some groups of people. Given the increasing frequency of multiple risk factors for suicide, such as loneliness, financial strain, and uncertainty, it is

understandable that there have been widespread concerns that COVID-19 could increase rates of suicide [17, 21, 22].

However, reassuringly the data from the early phase of the pandemic suggest that, in most countries (for which there are data), suicide rates have not increased [23]. For instance, UK data from 2020 indicates that there has not been a marked increase in suicide rates post-lockdown in England and Wales [24]. Indeed, the rate of suicide deaths in 2020 for England and Wales were 10.0/100,000 compared to 11.0/100,000 during 2019 [25].

A large international study conducted by Pirkis and colleagues [26], under the auspices of the International COVID-19 Suicide Prevention Research Collaboration, investigated rates of suicide in the early stages of the pandemic, and including available data from 21 countries around the world (16 of which were high-income countries and the remaining five upper-middle-income countries). Real-time data up to July 2020 was analyzed and compared to pre-pandemic suicide rates; with the observed suicide data compared to the expected rates based on the underlying time-based trends. Controlling for seasonal and time trends, the authors found that during the early months of the COVID-19 pandemic there were often no changes, or some decreases, in rates of suicide deaths recorded by these countries. Despite this finding, the authors recommend remaining vigilant as the longer-term mental health and economic effects of the pandemic develop. A notable limitation to the study is the inclusion of only high and upper-middle income countries, as data from lower-income countries was not available, although early evidence from some areas in India suggest an initial decline in suicide rates during the lockdown period [27].

For the most part, the early evidence from Pirkis et al. [26] present a more positive picture than anticipated in terms of the rates of suicide during the early stages of the pandemic. Indeed, a living systemic review synthesizing the global COVID-19 research literature on self-harm and suicidal behavior throughout the pandemic [23] has also reported similar findings. Overall, the literature to date indicates that there has not been a consistent rise in suicidal behavior during the pandemic, although there is evidence of adverse economic effects and a rise in levels of distress in the community. Additionally, there has been evidence of a reduction in presentations to hospital for self-harm and self-poisoning during the early stages of the pandemic (e.g., Refs. [28, 29]). Although it is important to highlight that an increase post-lockdown has been reported [29], and the authors suggest that people who have self-harmed may not have sought medical attention in the hospital setting due to the pandemic.

However, data from some countries such as Japan suggest that it is still too early to observe the full impact of the pandemic on suicidal behavior. For instance, the first cases of COVID-19 were recorded in Japan during January 2020; as a result the onset of COVID-19 may have been earlier in Japan than in other countries [30]. Indeed, at the beginning of the pandemic Japan recorded a decrease in the rates of suicide, however, suicide rates have since risen to higher than pre-pandemic levels [26, 30, 31]. Additionally, the data from Japan have indicated that increases in suicide rates were more pronounced in young people (children and adolescents) and young women [30, 31].

Although there has been a rapid expansion of studies reporting on the impact of COVID-19 on suicidal behavior, many of these only provide an overview of population-level suicide rates during the pandemic [47]. It is important to note that the studies identifying groups within particular populations who may be at increased risk of suicide are sparse [23]. For example, there has been some research into suicide risk among those who have contracted COVID-19; however, specific research into other groups who have been directly impacted by COVID-19, such as frontline workers or those bereaved by COVID-19, is required [23]. John and colleagues [23] also highlight that the majority of the COVID-19 research has been conducted in higher income countries; this dearth in research in low- and middle-income countries needs to be addressed. More generally, we need to improve the recording and reporting of suicide data and ensure that as close to real-time data as possible are collected and made available.
